(Dated: November 18, 2018)

We show that charge noise S_Q in Josephson qubits can be produced by fluctuating two level systems (TLS) with electric dipole moments in the substrate using a flat density of states. At high frequencies the frequency and temperature dependence of the charge noise depends on the ratio J/J_c of the electromagnetic flux J to the critical flux J_c . It is not widely appreciated that TLS in small qubits can easily be strongly saturated with $J/J_c \gg 1$. Our results are consistent with experimental conclusions that $S_Q \sim 1/f$ at low frequencies and $S_Q \sim f$ at high frequencies.

Noise and decoherence are a major obstacle to using superconducting Josephson junction qubits to construct quantum computers. Recent experiments [1, 2] indicate that a dominant source of decoherence is two level systems (TLS) in the insulating barrier of the tunnel junction as well as in the dielectric material used to fabricate the circuit. It is believed that these TLS fluctuators lead to low frequency 1/f charge noise $S_Q(f)$ [3, 4, 5, 6, 7]. However, at high frequencies, one experiment finds that the charge noise increases linearly with frequency [8]. This has prompted some theorists to use a TLS density of states linear in energy [9] which is contrary to the constant density of states that has been so successful in explaining the low temperature properties of glasses such as the specific heat that is linear in temperature [10]. A linear distribution has been proposed in conjunction with a Cooper pair tunneling into a pair of electron traps [11], and with electron hopping between Kondo-like traps to account for the charge noise [12].

However, these previous theoretical efforts have neglected the important issue of the saturation of the two level systems. Dielectric (ultrasonic) experiments on insulating glasses at low temperatures have found that when the electromagnetic (acoustic) energy flux J used to make the measurements exceeds the critical flux J_c , the dielectric (ultrasonic) power absorption by the TLS is saturated, and the attenuation decreases [2, 13, 14, 15, 16]. The previous theoretical efforts to explain the linear increase in the charge noise in Josephson junctions assumed that the TLS were not saturated, i.e., that $J \ll J_c$. This seems sensible since the charge noise experiments were done in the limit where the qubit absorbed only one photon. However, stray electric fields could saturate TLS in the dielectric substrate as the following simple estimate shows. We can estimate the voltage V across the capacitor associated with the substrate and ground plane beneath the Cooper pair box by setting $CV^2/2 = \hbar\omega$ where $\hbar\omega$ is the energy of the microwave photon. We estimate the capacitance $C = \varepsilon_0 \varepsilon A/L \sim 7$ aF using the area $A = 40 \times 800 \text{ nm}^2$ [8] of the Cooper pair box, the thickness L = 400 nm of the substrate [8],

and the dielectric constant $\varepsilon = 10$. Using $\omega/2\pi = 10$ GHz, we obtain a voltage of $V \sim 1.4$ mV. The substrate thickness L of 400 nm yields an electric field of $E \sim 3.4 \times 10^3$ V/m. For amorphous SiO₂ at f = 7.2GHz and SiN_x at f = 4.7 GHz, the critical rms voltage $V_c \sim 0.2 \ \mu V$ [2], and with a capacitor thickness of 300 nm, the critical field is $E_c \sim 0.7 \; \mathrm{V/m}$ at $T=25 \; \mathrm{mK.}$ So $E/E_c \sim 5 \times 10^3$, and $J/J_c = (E/E_c)^2 \sim 2 \times 10^7 \gg 1$. A similar estimate shows that a single photon would even more strongly saturate resonant TLS in the insulating barrier of the tunnel junction, again resulting in $J/J_c \gg 1$. However, there are only a few TLS in the oxide barrier of a small tunnel junction. (For a parallel plate capacitor with a specific capacitance of 60 fF/ μ m². L = 1.5 nm, $A = 1 \ \mu m^2$ and a dielectric constant of 10, the volume is $\Omega = 1.5 \times 10^{-21}$ m³. With a density of states $P_0 \simeq 10^{45}/(Jm^3) \simeq 663/h \text{GHz} \mu \text{m}^3$, there are only 2 TLS with an energy splitting less than 10 GHz.) A single fluctuator would have a Lorentian noise spectrum. The presence of 1/f noise implies many more than 2 fluctuators. It is likely that these additional fluctuators are in the substrate. Our main point is that TLS in small devices are easily saturated.

In this letter we explore the consequences of this saturation. We find that at high frequencies $(\hbar \omega \gg k_B T)$, the frequency and temperature dependence of the charge noise depends on the ratio $J/J_c(\omega, T)$ of the electromagnetic flux J to the critical value $J_c(\omega, T)$ which is a function of frequency ω and temperature T. Starting from the fluctuation-dissipation theorem, we show that the charge noise is proportional to the dielectric loss tangent $\tan \delta$. We then calculate the dielectric loss tangent due to fluctuating TLS with electric dipole moments [10, 14, 17]. At low frequencies we recover 1/f noise. At high frequencies tan δ is proportional to $1/\sqrt{1+(J/J_c(\omega,T))}$. In the saturation regime $(J \gg J_c(\omega, T))$, tan δ and hence, the charge noise, are proportional to $\sqrt{J_c(\omega,T)/J}$. Some TLS experiments [18, 19, 20] indicate that $J_c(\omega, T) \sim$ $\omega^2 T^2$ which implies that at high frequencies the charge noise and the dielectric loss tangent would increase linearly in frequency if $J \gg J_c(\omega, T)$. Unlike previous theoretical efforts, we use the standard TLS density of states that is independent of energy, and can still obtain charge noise that increases linearly with frequency in agreement with the conclusions of Astafiev *et al.* [8].

In applying the standard model of two level systems to Josephson junction devices, we consider a TLS that sits in the insulating substrate or in the tunnel barrier, and has an electric dipole moment \mathbf{p} consisting of a pair of opposite charges separated by a distance d. The electrodes are located at z = 0 and z = L and kept at the same potential. The angle between \mathbf{p} and z-axis which lies perpendicular to the plane of the electrodes is θ_0 . The dipole flips and induces charge fluctuations on the electrodes. These induced charges are proportional to the z-component of the dipole moment, i.e., $Q = |p \cos \theta_0/L|$.

The TLS is in a double-well potential with a tunneling matrix element Δ_0 and an asymmetry energy Δ [10]. The Hamiltonian of a TLS in an external ac field can be written as $H = H_0 + H_1$, where $H_0 = \frac{1}{2}(\Delta \sigma_z + \Delta_0 \sigma_x)$, and $H_1 = -\sigma_z \mathbf{p} \cdot \boldsymbol{\xi}_{ac}(t)$. Here $\sigma_{x,z}$ are the Pauli spin matrices and $\boldsymbol{\xi}_{ac}(t) = \boldsymbol{\xi}_{ac} \cos \omega t$ is a small perturbing ac field of frequency ω that couples to the TLS electric dipole moment. After diagonalization, the TLS Hamiltonian becomes $H_0 = \frac{1}{2}E\sigma_z$, where E is the TLS energy splitting (i.e., $E = \sqrt{\Delta^2 + \Delta_o^2}$) and, in the new basis, the perturbing Hamiltonian is $H_1 = -(\sigma_z \Delta/E + \sigma_x \Delta_0/E) \mathbf{p} \cdot \boldsymbol{\xi}_{ac}(t).$ The complete TLS Hamiltonian is similar to the Hamiltonian $H_S = -\gamma \mathbf{S} \cdot \mathbf{B}$ for a spin 1/2 particle in a magnetic field given by $\mathbf{B}(t) = \mathbf{B}_0 + \mathbf{B}_1(t)$, where the static field is $-\hbar\gamma \mathbf{B}_0 = (0, 0, E)$ and the rotating field is $\hbar \gamma \mathbf{B}_1(t) = (2\Delta_0/E, 0, 2\Delta/E)\mathbf{p} \cdot \boldsymbol{\xi}_{ac} \cos \omega t$ [21]. γ is the gyromagnetic ratio and $\mathbf{S} = \hbar \boldsymbol{\sigma}/2$. Therefore, the equations of motion of the expectation values of the spin components are given by the Bloch equations [22] with the longitudinal and the transverse relaxation times, T_1 and T_2 . In the standard model, an excited two-level system decays to the ground state by emitting a phonon. The longitudinal relaxation rate, T_1^{-1} , is given by [10]

$$T_1^{-1} = aE\Delta_o^2 \coth\left(\frac{E}{2k_BT}\right),\tag{1}$$

where $a = \left[\gamma_d^2 / (2\pi\rho\hbar^4)\right] \left[(1/c_\ell^5) + (2/c_t^5) \right]$ where ρ is the mass density, c_ℓ is the longitudinal speed of sound, c_t is the transverse speed of sound, and γ_d is the deformation potential. The distribution of TLS parameters can be expressed in terms of E and T_1 : $P(E, T_1) =$ $P_0/(2T_1\sqrt{1-\tau_{min}(E)/T_1})$ [10, 23] where P_0 is a constant. The minimum relaxation time $\tau_{min}(E)$ corresponds to a symmetric double–well potential (i.e., E = Δ_0). The transverse relaxation time T_2 represents the broadening of levels due to their mutual interaction [24].

General Expression for Charge Noise: We derive a general expression valid at all frequencies for the charge noise in terms of the dielectric loss tangent $\tan \delta(\omega) = \varepsilon''(\omega)/\varepsilon'(\omega)$, where $\varepsilon'(\omega)$ and $\varepsilon''(\omega)$ are the real and imaginary parts of the permittivity.

According to the Wiener-Khintchine theorem, the charge spectral density $S_Q(\omega)$ is twice the Fourier transform $\Psi_Q(\omega)$ of the autocorrelation function of the fluctuations in the charge. From the fluctuation-dissipation theorem, the charge noise is given by:

$$S_Q(\boldsymbol{k},\omega) = \frac{4\hbar}{1 - \mathrm{e}^{-\hbar\omega/k_B T}} \chi_Q''(\boldsymbol{k},\omega), \qquad (2)$$

where Q is the induced (bound) charge and $\chi_Q''(\mathbf{k},\omega)$ is the Fourier transform of $\chi_Q''(\mathbf{r},t;\mathbf{r}',t') = \langle [Q(\mathbf{r},t),Q(\mathbf{r}',t')] \rangle / 2\hbar$. We use $Q = \int \mathbf{P} \cdot d\mathbf{A}$, where \mathbf{P} is the electric polarization density, and choose P_z and $d\mathbf{A} \| \hat{z}$ since $Q \sim |p_z|$ to find $\chi_Q''(\mathbf{k},\omega) = \varepsilon_o A^2 \chi_{P_z}'(\mathbf{k},\omega)$, where ε_0 is the vacuum permittivity, A is the area of a plate of the parallel plate capacitor with capacitance C, and $\chi_{P_z}''(\mathbf{k},\omega)$ is the imaginary part of the electric susceptibility. Setting $\mathbf{k} = 0$, and using $\varepsilon_o \chi_{P_z}''(\omega) = \varepsilon'(\omega) \tan \delta(\omega)$, and $C = \varepsilon' A/L$, we find

$$S_Q(\omega) = \frac{4\hbar C}{1 - e^{-\hbar\omega/k_B T}} \tan \delta(\omega), \qquad (3)$$

where $S_Q(\omega) \equiv S_Q(\mathbf{k} = 0, \omega)/\Omega$, the volume of the capacitor is $\Omega = AL$, and $\varepsilon'(\omega) = \varepsilon' + \varepsilon_{TLS}(\omega) \simeq \varepsilon' = \varepsilon_0 \varepsilon_r$ where ε_r is the relative permittivity. The frequency dependent $\varepsilon_{TLS}(\omega)$ produced by TLS is negligible compared to the constant permittivity ε' [10].

The dynamic electric susceptibilities $(\chi'(\omega), \chi''(\omega)),$ and hence the dielectric loss tangent, can be obtained by solving the Bloch equations [14, 16, 25]. (Shnirman *et* al. [9] gave a reformulation of the Bloch equations for TLS in terms of density matrices and the Bloch-Redfield theory.) The electromagnetic dispersion and attenuation due to TLS has two contributions. First there is the relaxation process due to the modulation of the TLS energy splitting by the incident wave resulting in readjustment of the equilibrium level population. This is described by $\chi_z(\omega)$ that comes from solving the Bloch equations for S_z which is associated with the population difference of the two levels. The second process is the resonant absorption by TLS of phonons with $\hbar \omega = E$. Resonance is associated with $\chi_{\pm}(\omega) = \chi_x(\omega) \pm i\chi_y(\omega)$ since σ_x and σ_y are associated with transitions between the two levels. The total dielectric loss tangent is the sum of these two contributions: $\tan \delta = \tan \delta_{REL} + \tan \delta_{RES}$. The steady-state solution of the Bloch equations and the resulting dielectric loss tangent for TLS are well known [14, 16, 21, 25].

In the steady-state regime the experimental values for the relaxation times T_1 and T_2 are considered small compared to the electromagnetic pulse duration, t_p . One might ask if one should use the transient solution [21] of the Bloch equations since the pulse applied to superconducting qubits is often extremely short, $t_p \sim 10^{-10}$ sec [8]. We find that the transient z-component of the magnetization [21], $S_z^0(t)$, decays exponentially to the equilibrium value denoted by $S_{z,eq}^0$, i.e.: $S_z^0(t) = S_{z,eq}^0 + \exp(-t/T^*)[S_z^0(0) - S_{z,eq}^0]$, where $S_z^0(0)$ is the initial value of S_z^0 and $S_{z,eq}^0 = -\hbar \tanh(E/2k_BT)/2$. The transient relaxation time T^* is given by

$$T^{\star} = \frac{T_1}{1 + (J/J_c(\omega, T)) \times g(\omega, \omega_0, T_2)}, \quad \text{where} \\ g(\omega, \omega_0, T_2) = \frac{1}{1 + T_2^2(\omega - \omega_0)^2} + \frac{1}{1 + T_2^2(\omega + \omega_0)^2}.$$
(4)

Here $J/J_c(\omega, T) = (\mathbf{p}' \cdot \boldsymbol{\xi}_{ac}/\hbar)^2 T_1 T_2$, $\mathbf{p}' = (\Delta_0/\epsilon)\mathbf{p}$ represents the induced TLS dipole moment, and $\omega_0 = \gamma B_0 = -E/\hbar$. In the saturated regime, for $J \gg J_c(\omega, T)$, we find that $T^* \approx [T_2(\mathbf{p}' \cdot \boldsymbol{\xi}_{ac}/\hbar)^2]^{-1}$. Using p' = 3.7 D, $\boldsymbol{\xi}_{ac} = 3.4 \times 10^3$ V/m, and $T_2 = 8 \ \mu s$ at T = 0.1 K [19, 21] yields $T^* \simeq 8 \times 10^{-13}$ sec at resonance when $\omega/2\pi \simeq \omega_0/2\pi = 10$ GHz. This value is much shorter than the typical pulse length used in the Josephson junction qubits experiments and therefore the results from steady-state saturation theory can be used. However, in the unsaturated regime, $T^* \approx T_1 \approx 8 \times 10^{-8}$ sec at T = 0.1 K, so transient effects can be important.

High Frequency Charge Noise: At high frequencies (HF) ($\hbar \omega \gg k_B T$) the dielectric loss tangent is dominated by resonant (RES) absorption processes (i.e., $\tan \delta_{HF} \simeq \tan \delta_{RES}$) [10, 14, 26]:

$$\tan \delta_{HF}(\omega, T) = \frac{\pi p^2 P_0}{3\varepsilon'} \tanh(\hbar \omega/2k_B T) \frac{1}{\sqrt{1 + J/J_c(\omega, T)}}$$
(5)

where $J_c(\omega, T) = 3\hbar^2 \varepsilon' v/(2p^2 T_1 T_2)$ and v is the speed of light in the solid. Eq. (5) comes from integrating over the TLS distribution [14]. However, if no integration is done due to the small number N_0 of TLS, e.g., in the tunnel junction barrier, $\tan \delta_{HF}(\omega, T) =$ $N_0 p^2 T_2/(3\varepsilon'\hbar\Omega) \times \tanh(\hbar\omega/2k_B T)[1+J/J_c(\omega, T)]^{-1}$. So for high intensities the $(J/J_c)^{-1/2}$ dependence of $\tan \delta$ becomes a $(J/J_c)^{-1}$ dependence. The frequency and temperature dependence of $\tan \delta$, and hence of $S_Q(\omega)$, depends on $J/J_c(\omega, T)$.

At low intensities $(J \ll J_c(\omega, T))$ in the unsaturated steady-state resonant absorption regime, the dielectric loss tangent is constant:

$$\tan \delta_{HF} \simeq \pi p^2 P_0 / \left(3\varepsilon' \right) \tag{6}$$

For $\varepsilon_r = 10$, $P_0 \approx 10^{45} (\text{Jm}^3)^{-1}$ [27, 28], and p = 3.7 D (which corresponds to the dipole moment of an OH⁻ impurity [29]), we estimate $\tan \delta_{HF} \approx 1.8 \times 10^{-3}$. This result agrees well with the value of $\delta \simeq 1.6 \times 10^{-3}$ reported in Ref. [2]. In this regime the charge noise is constant: $S_Q/e^2 \simeq 4\pi \hbar C p^2 P_0/(3e^2\varepsilon')$. For C = 7 aF, $S_Q/e^2 \simeq 2 \times 10^{-16}$ Hz⁻¹.

For high field intensities $J \gg J_c(\omega, T)$, we obtain $\tan \delta_{HF} = \pi p^2 P_0/(3\varepsilon') \times \sqrt{J_c(\omega, T)/J}$. The $J^{-1/2}$ dependence of $\tan \delta$ has been found for materials such as

amorphous SiO_2 and amorphous SiN_x [2]. In the saturated resonant absorption regime the charge noise is given by

$$\frac{S_Q(\omega,T)}{e^2} \simeq \frac{4\hbar C}{e^2} \frac{\pi p^2 P_0}{3\varepsilon'} \sqrt{\frac{J_c(\omega,T)}{J}}.$$
 (7)

So the frequency and temperature dependence of the noise is determined by T_1 and T_2 : $S_O(\omega, T)$ \sim $\sqrt{J_c(\omega,T)} \sim (T_1T_2)^{-1/2}$. Experiments and theory find that $T_2^{-1} \sim T^m$ where *m* ranges from 1 to 2.2 [19, 20, 21, 24, 30, 31, 32, 33]. T₂ decreases with increasing frequency [20] but the exact frequency dependence is not known, so we will ignore it in what follows. T_1 in the symmetric case with $\hbar\omega = E = \Delta_o$ is given by Eq. (1): $T_1^{-1} \sim \omega^3$, implying that at high frequencies and intensities $S_Q(\omega,T) \sim \omega^{3/2} T^{m/2}$, where m/2 varies between 0.5 and 1.1. If there are only a very few TLS, then $S_Q(\omega,T) \sim J_c(\omega,T) \sim (T_1T_2) \sim \omega^3 T^m$. Although the experimental frequency dependence was reported to be linear [8], the scatter in the data is large enough to allow for a steeper frequency dependence. In fact, the dependence is much steeper for data at the degeneracy point.

Experimental measurements [15] on SiO₂ at f = 10 GHz and 0.4 < T < 1 K find $J_c(\omega, T) = 25$ mW/cm² × $(T/0.4\text{K})^4$, and that $J/J_c(\omega, T)$ varies between 10^{-2} and 10^4 . This implies that the charge noise S_Q/e^2 should vary between 2×10^{-16} Hz⁻¹ and 2×10^{-18} Hz⁻¹ at T = 0.1 K. However, other measurements have found $J_c(\omega, T) \sim \omega^n T^2$ [14], where n is equal to either 0 [19, 34] or 2 [18, 20]. If $J_c(\omega, T) \sim \omega^2$, then $\tan \delta(\omega) \sim \omega$, and $S_Q(\omega) \sim \omega$ at high frequencies and high intensities, which agrees with the recent experiments by Astafiev *et al.* [8]. It would be interesting measure the temperature dependence of S_Q experimentally.

While currently there are no direct experimental measurements of the HF charge noise, in Ref. [8] $S_Q(\omega)$ has been deduced by measuring the qubit relaxation rate Γ_1 versus the gate induced charge q for a Cooper pair box with a capacitance C_b , Josephson energy E_J (in the GHz range), and electrostatic energy $U = 2eq/C_b$. From $\Gamma_1 =$ $\pi S_U(\omega) \sin^2(\theta)/2\hbar^2$, where $\sin \theta = E_J^2/(E_J^2 + U^2)$ and $\hbar \omega$ equals the qubit energy splitting $(\hbar\omega = (U^2 + E_T^2)^{1/2}),$ and $S_U(\omega) = (2e/C_b)^2 S_q(\omega)$, they obtained the charge noise $S_q(\omega)$ at high frequency [8]. We can compare our results with these experiments by reversing this procedure to find $\Gamma_1(q)$ from $S_q(\omega)$. We find for saturated TLS that Γ_1 at the maximum (q = 0) is of order 10^8 s^{-1} [35] and increases as E_I^2 in good quantitative agreement with the experimental results from Fig. 2 and 3 of Astafiev etal. [8]. We find that $\Gamma_{1,max}$, the maximum value of Γ_1 (at q = 0), increases with the frequency $f = E_J/h$ in the saturated regime but is independent of frequency at low intensities $J \ll J_c(\omega, T)$.

Low Frequency Charge Noise: We now show that we

can recover the low frequency 1/f charge noise using Eq. (3). At low frequencies (LF) where $\hbar\omega \ll k_B T$, only the relaxation absorption process contributes: $\tan \delta_{LF} \simeq$ $\tan \delta_{REL} = \pi p^2 P_0/(6\varepsilon')$ [17]. Eq. (3) gives [12, 36]

$$\frac{S_Q(f)}{e^2} = \frac{2k_B T}{e^2/2C} \tan \delta_{LF} \frac{1}{2\pi f} = \frac{1}{3} \Omega P_0 k_B T \left(\frac{p}{eL}\right)^2 \frac{1}{f}.$$
(8)

To estimate the value of S_Q , we use p = 3.7 D, $P_0 \approx 10^{45} (\text{Jm}^3)^{-1}$, L = 400 nm, and $A = 40 \times 800$ nm². At T = 100 mK and f = 1 Hz, we obtain $S_Q/e^2 = 2 \times 10^{-7} \text{ Hz}^{-1}$, which is comparable to the experimental value of $4 \times 10^{-6} \text{ Hz}^{-1}$ deduced from current noise [7]. As Eq. (8) shows, the standard TLS distribution gives low frequency 1/f charge noise that is linear in temperature, while experiments find a quadratic temperature dependence [6, 7]. This implies that at low frequencies and temperatures contributions from other mechanisms may dominate the charge noise [11].

To conclude, we have shown that the frequency and temperature dependence of high frequency charge noise in Josephson junction devices depends on the ratio $J/J_c(\omega, T)$ of the electromagnetic flux to the critical flux. Using the standard theory of two level systems with a flat density of states, we find that the charge noise at high frequencies can increase linearly with frequency and temperature if $J/J_c(\omega, T) \gg 1$. This agrees with the conclusions of recent experiments on the high frequency charge noise in Josephson junction qubits [8] which our estimates show are in the strongly saturated limit.

- [28] In Refs. [2, 15] an intrinsic dielectric loss of $\approx 2 \times 10^{-3}$ has been measured in vitreous silica Suprasil I and amorphous SiO₂, respectively, at 10 GHz and $T \leq 100$ mK. Assuming $\epsilon_r = 10$, Eq. (6) gives $P_0 \approx 10^{45} \text{ (Jm}^3)^{-1}$.

- [35] The parameters used to find Γ_1 were: $P_0 = 10^{45} (\mathrm{Jm}^3)^{-1}$ [27, 28], p = 3.7 D, $\xi_{ac} = 3.4 \times 10^3$ V/m, $\varepsilon_r = 10$, $C_b = 600$ aF [8], and T = 50 mK. We found T_1 from Eq. (1) using $a = 4.27 \times 10^{76} (\mathrm{J}^3 \mathrm{sec})^{-1}$ [10, 21] and $E = \Delta_o$. For T_2 we have used $T_2 \simeq 8 \times 10^{-7}/T$ [19, 21].
