We analyze the fractional quantization of the ballistic conductance associated with the light and heavy holes bands in Si, Ge and GaAs systems. It is shown that the formation of the localized hole state in the region of the quantum point contact connecting two quasi-1D hole leads modifies drastically the conductance pattern. Exchange interaction between localized and propagating holes results in the fractional quantization of the ballistic conductance different from those in electronic systems. The value of the conductance at the additional plateaux depends on the offset between the bands of the light and heavy holes,  $\Delta$ , and the sign of the exchange interaction constant. For  $\Delta = 0$  and ferromagnetic exchange interaction, we observe additional plateaux around the values  $7e^2/4h$ ,  $3e^2/h$  and  $15e^2/4h$ , while antiferromagnetic interaction plateaux are formed around  $e^2/4h$ ,  $e^2/h$  and  $9e^2/4h$ . For large  $\Delta$ , the single plateau is formed at  $e^2/h$ .

PACS numbers: 73.23.-b, 73.21.Hb, 72.25.Mk

The progress in nanotechnology allowed the fabrication of the quasi- one dimensional mesoscopic components in which the transport of the carriers has a ballistic character and is not accompanied by the Joule losses<sup>1,2</sup>. The conductance through these objects, *G*, is proportional to the number of the open 1D propagation modes, *N*, which can be modulated by the application of the perpendicular gate voltage,  $V_g$ . Tuning  $V_g$  one observes ballistic conductance staircase with plateaus at integer multiples of the conductance quantum  $G_0 = 2e^2/h$ , where the factor 2 reflects the spin degeneration of the bands. This result can be understood in frameworks of the model of noninteracting electrons<sup>3</sup>.

However, in the region of small carrier concentrations, an additional plateau is observed near  $0.7G_0$ . In external magnetic field it evolves smoothly into the spin-polarized conductance plateau at  $0.5G_0^{4,5}$  thus indicating that "0.7 feature" can be connected with spin. Later experiments have shown a zero-bias peak (ZBP) in the differential conductance and a peculiar temperature dependence of "0.7 feature"<sup>6</sup>, which led to the proposal that it could be a Kondo-type phenomenon<sup>7</sup> connected with dynamical spin polarization. However, more recent experiments demonstrated the absence of any ZBP at least for some experimental configurations<sup>8</sup> thus contradicting the Kondo interpretation and supporting the models based on the static spin polarization of the electrons in the region of the quantum point contact (OPC) leading to the appearence of the spin  $gap^{9,10,11}$ . The formation of the spin polarized state in quantum wires and quantum point contacts was predicted theoretically<sup>12,13,14</sup> and obtained additional support from recent experimental studies<sup>8,15</sup>.

Within the model of the spontaneous spin polarization of the contact the appearence of the "0.7 feature" can be explained as follows. Suppose that QPC contains a single localized electron which affects the propagating carriers via exchange interaction. Since the latter is defined by the mutual orientation of their spins, the transmission coefficient through the QPC with a magnetic moment is spin-dependent. Besides, if the triplet state energy is lower than the singlet state one, the potential barrier formed by the QPC region for the carrier in the singlet configuration is higher than for the triplet state.

Therefore, at small concentration of carriers, the ingoing electron in the triplet configuration passes the QPC freely, while the carriers in the singlet configuration are reflected, thereby defining the principal contribution of the triplet pairs to the total conductivity. In zero magnetic fields the probability of the realization of the triplet configuration is equal to 3/4 against 1/4 for the singlet one, and thus the OPC conductance in the regime considered reads  $G = 3/4G_0^{16}$ . On the contrary, if the singlet configuration is energetically preferable, the conductance should be equal to  $G = 1/4G_0$ . The application of the external magnetic field leads to the spin polarization of both the propagating and localised carriers thus giving rise to the conductance value equal to  $G = 1/2G_0$  in accordance with experimental data. If more than one unpaired electrons is localized on the QPC, the value of the conductance on the additional plateau decreases<sup>17</sup>, which can explain the evolution of "0.7 feature" into "0.5 feature" with the increase of the length of the  $QPC^{18}$ .

In this work we analyze the ballistic conductance associated with the holes bands in Si, Ge and GaAs quasi 1D systems. We consider the transmission of propagating hole states facing effective potential barriers, generated by a spin-dependent interaction with a localized hole, supposedly, present in the region of the QPC<sup>19</sup>. As it was mentioned above for electrons this model qualitatively reproduces the major characteristics observed in the 0.7 experiments<sup>20</sup>. Due to the difference of spin structure for electrons and holes one can expect that the effect of exchange interaction on ballistic conductance will be qualitatively different in these two cases.

The valence bands of bulk Si, Ge and GaAs present two branches: the heavy hole band, with spins  $J_z^{hh} = \pm 3/2$ , and the light hole band, with spins  $J_z^{lh} = \pm 1/2$ . In quasi-1D systems due to the effects of confinement the energetic splitting  $\Delta$ appears between these two bands, which depends on the width of the quantum wire, the difference in the effective masses of the light and heavy holes,  $m_{lh}$  and  $m_{hh}$ , and strains. In our further consideration we will take account of only the lowest bands of the light and heavy holes<sup>21</sup>. We suppose also that the propagating and localized holes interact only in the region of the QPC having the length *L*. The Hamiltonian of the system can be thus cast in the form:

$$H = \begin{cases} \frac{\hbar^2 k^2}{2m_{hh,lh}}, & x < 0, x > L\\ \frac{\hbar^2 k^2}{2m_{hh,lh}} + V_{dir} + V_{ex} \mathbf{J}_p \cdot \mathbf{J}_l, & x \in [0, L] \end{cases}$$
(1)

where the indices p and l correspond to the propagating and localized holes respectively,  $V_{dir} > 0$  is the matrix element of the direct interaction and  $V_{ex}$  is the matrix element of the exchange interaction ( $V_{ex} < 0$  for ferromagnetic interacting and  $V_{ex} > 0$  for antiferromagnetic interaction). It should be noted that many-body correlations of the Kondo type can lead to the temperature-dependent renormaliation of the exchange interaction constant  $V_{ex}^{22}$  which can manifest itself in non-trivial temperature dependence of the "0.7 feature" for both electron<sup>6</sup> and hole systems. The analysis of this dependence, however, lies beyond the scope of the present work.

In the  $\{|m_n, m_l\rangle\}$  basis the Hamiltonian in the region of the QPC can be represented by a block-diagonal  $16 \times 16$  matrix

$$H = diag \left[ H^{(+3)}; H^{(+2)}; H^{(+1)}; H^{(0)}; H^{(-1)}; H^{(-2)}; H^{(-3)} \right],$$
(2)

with each block associated with a given (superscript) value of the z-component,  $J_{T,z} = m_p + m_l$ , of the total angular momentum of the pair of holes,  $\mathbf{J}_T = \mathbf{J}_p + \mathbf{J}_l$ :

$$H^{(\pm 2)} = \begin{pmatrix} E_{hh}^{0} + \frac{3}{4}V_{ex} + \Delta & \frac{3}{2}V_{ex} \\ \frac{3}{2}V_{ex} & E_{lh}^{0} + \frac{3}{4}V_{ex} + \Delta \end{pmatrix}, \quad H^{(\pm 1)} = \begin{pmatrix} E_{hh}^{0} - \frac{3}{4}V_{ex} + \Delta & V_{ex}\sqrt{3} & 0 \\ V_{ex}\sqrt{3} & E_{lh}^{0} + \frac{1}{4}V_{ex} + 2\Delta & V_{ex}\sqrt{3} \\ 0 & V_{ex}\sqrt{3} & E_{lh}^{0} - \frac{3}{4}V_{ex} + \Delta \end{pmatrix},$$
$$H^{(0)} = \begin{pmatrix} E_{hh}^{0} - \frac{9}{4}V_{ex} & \frac{3}{2}V_{ex} & 0 & 0 \\ \frac{3}{2}V_{ex} & E_{lh}^{0} - \frac{1}{4}V_{ex} + 2\Delta & 2V_{ex} & 0 \\ 0 & 2V_{ex} & E_{lh}^{0} - \frac{1}{4}V_{ex} + 2\Delta & \frac{3}{2}V_{ex} \\ 0 & 0 & \frac{3}{2}V_{ex} & E_{hh}^{0} - \frac{9}{4}V_{ex} \end{pmatrix}, \quad H^{(\pm 3)} = E_{hh}^{0} + \frac{9}{4}V_{ex}, \tag{3}$$

where  $E_{hh,lh}^0 = \frac{\hbar^2 k^2}{2m_{hh,lh}} + V_{dir}$ . The general expression for the conductance of the system at zero temperature is given by

$$G(E_F) = \frac{Ne^2}{h} \sum_{m_p, m_l, m'_p, m'_l = \pm 3/2, \pm 1/2} \alpha_{m_p}(E_F) \alpha_{m_l}(E_F) \\ \times \left| A(E_F)_{m_p, m_l \to m'_p, m'_l} \right|^2 \delta_{m_p + m_l, m'_p + m'_l}.$$
 (4)

where N is a number of the open propagating modes, N = 2if  $E_F < \Delta$  and N = 4 if  $E_F > \Delta$ ,  $\alpha_{m_{p,l}}(E_F)$  are probabilities to find localized and propagating hole in the state with spin projection  $m_{p,l}$ . In the absence of an external magnetic field  $\alpha_{\pm 3/2_{p,l}}(E_F) = 1/2, \alpha_{\pm 1/2_{p,l}}(E_F) = 0$  if  $E_F < \Delta$  and  $\alpha_{\pm 3/2_{p,l}}(E_F) = \alpha_{\pm 1/2_{p,l}}(E_F) = 1/4$  if  $E_F > \Delta$ . The transmissions amplitudes,  $A_{m_p,m_l \to m'_p,m'_l}$ , are determined by finding the stationary states of the corresponding propagating hole facing the effective potential barrier described by the above  $H^{(J_{T,z})}$ matrices. Considering the conservation of the total spin, represented by the Kronecker- $\delta$ , we will get 44 different transmissions amplitudes. In the absence of an external magnetic field we will have the invariance as respect to the spin inversion, and this number will be reduced to 22.

The transmissions amplitudes associated with the initial states  $\left|+\frac{3}{2},+\frac{3}{2}\right\rangle$  and  $\left|-\frac{3}{2},-\frac{3}{2}\right\rangle$ , corresponding to the values  $J_{T,z} = \pm 3$ , are spin conservative and thus determined by solving the problem of a free particle with kinetic energy  $\hbar^2 k_F^2/2m_{hh}$  facing a square barrier of width L and potential  $V_{dir} + \frac{9}{4}V_{ex}$ . The first non-trivial spin-flip processes are associated with the states with  $J_{T,z} = \pm 2$ . The transmission amplitudes in this case can be determined from the procedure, which we show for instance when the initial spin configuration of the propagating and localized holes corresponds to the state  $\left|+\frac{3}{2},+\frac{1}{2}\right\rangle$ . The wavefunction of the propagating hole reads

$$\begin{split} \Psi_{I} &= \begin{pmatrix} 1 \\ 0 \end{pmatrix} e^{ik_{hh}x} + B_{\left| + \frac{3}{2}, + \frac{1}{2} \right\rangle \rightarrow \left| + \frac{3}{2}, + \frac{1}{2} \right\rangle} \begin{pmatrix} 1 \\ 0 \end{pmatrix} e^{-ik_{hh}x} \\ &+ B_{\left| + \frac{3}{2}, + \frac{1}{2} \right\rangle \rightarrow \left| + \frac{1}{2}, + \frac{3}{2} \right\rangle} \begin{pmatrix} 0 \\ 1 \end{pmatrix} e^{-ik_{lh}x}, \quad x < 0, \\ \Psi_{II} &= \mathbf{X}_{1} \left( C_{1}^{+} e^{ik_{1}x} + C_{1}^{-} e^{-ik_{1}x} \right) \\ &+ \mathbf{X}_{2} \left( C_{2}^{+} e^{ik_{2}x} + C_{2}^{-} e^{-ik_{2}x} \right), \quad x \in [0, L], \end{split}$$
(5)  
$$\Psi_{III} &= \begin{pmatrix} 1 \\ 0 \end{pmatrix} A_{\left| + \frac{3}{2}, + \frac{1}{2} \right\rangle \rightarrow \left| + \frac{3}{2}, + \frac{1}{2} \right\rangle} e^{ik_{hh}x} \\ &+ \begin{pmatrix} 0 \\ 1 \end{pmatrix} A_{\left| + \frac{3}{2}, + \frac{1}{2} \right\rangle \rightarrow \left| + \frac{1}{2}, + \frac{3}{2} \right\rangle} e^{ik_{lh}x}, \quad x > L, \end{split}$$

where

$$\begin{pmatrix} 1\\0 \end{pmatrix} = \begin{vmatrix} +\frac{3}{2} \\ \end{pmatrix}, \begin{pmatrix} 0\\1 \end{pmatrix} = \begin{vmatrix} +\frac{1}{2} \\ \end{pmatrix}, k_{hh,lh} = \sqrt{\frac{2m_{hh,lh}E_F}{\hbar^2}},$$
(6)

 $\mathbf{X}_{1,2}$  are the eigenvectors of the matrix  $H^{(+2)}$  and the wave vectors  $k_{1,2}$  are determined self consistently in such a way that the eigenenergies,  $\epsilon_{1,2}^{(+2)}(k_{1,2})$ , correspond to the total energy of the system,  $E_F + \tilde{\Delta}$  (once that in the considered case we initially have a propagating heavy hole, with energy  $E_F$ , and a localized light hole, with energy  $\Delta$ ). The transmission and reflection amplitudes, A and B are found from the continuity conditions at x = 0, x = L. Analogous procedures must be

Figure 1: Steps of the quantum conductance staircase vc the chemical potential of carriers in a Si QPC for the ferromagnetic case. We considered the standard values of the Si light and heavy holes effective masses:  $m_{lh} = 0.16m_e$ ,  $m_{hh} = 0.49m_e$ . The different lines correspond to three different values of  $\Delta(meV) = 0, 0.45, 10$ . The direct and exchange interaction are estimated as  $V_{ex} \simeq -0.5meV$  and  $V_{dir} \simeq 1meV$ , the length of the contact as L = 50nm and we considered the temperature T = 0.5K. The vertical gray lines correspond to the values of the heights of the effective potential barriers,  $V_{dir} - 3V_{ex}/4$ ,  $V_{dir} - 11V_{ex}/4$  and  $V_{dir} - 15V_{ex}/4$ , whereas the dashed horizontal lines correspond to the values  $7e^2/4h$ ,  $3e^2/h$  and  $15e^2/4h$ . The inset shows a band structure of the 1D holes.

followed for all other possible initial states, grouping them in the sets of conserved  $J_{T,z}$  and diagonalizing corresponding blocks of the Hamiltonian  $H^{(\pm 1)}$  and  $H^{(0)}$ .

Figs.(1) and (2) show the conductance of a Si- based quantum well for various offsets between the bands of light and heavy holes. For ferromagnetic exchange interaction and moderate values of  $\Delta$  we observe plateaux close to the values  $7e^2/4h$ ,  $3e^2/h$  and  $15e^2/4h$ , (Fig.(1)). For antiferromagnetic interaction plateaux close to  $e^2/4h$ ,  $e^2/h$ and  $9e^2/4h$  are formed (Fig.(2)). Considering the values of total spin of the pair consisting of propagating and localized holes and counting the corresponding probabilities of realization, we can show that these values of conductance have a clear physical origin. The spin- dependent part of the Hamiltonian (1) can be rewritten as  $V_{ex}\mathbf{J}_{p}\cdot\mathbf{J}_{l} =$  $\frac{1}{2}V_{ex}\left(\mathbf{J}_{T}^{2}-\mathbf{J}_{p}^{2}-\mathbf{J}_{l}^{2}\right)=\frac{1}{2}V_{ex}\left[J_{T}\left(J_{T}+1\right)-3\left(3/2+1\right)\right], \text{ resulting in the values } 9V_{ex}/4, -3V_{ex}/4, -11V_{ex}/4 \text{ and } -15V_{ex}/4,$ for the possible absolute values of the total spin  $J_T = 3, 2, 1, 0$ , respectively. These values, summed with the direct interaction,  $V_{dir}$ , will define four different spin dependent heights of the effective potential barrier. The positive energy value of these heights are plotted as vertical lines in Figs.(1) and (2), and it is seen that they barely define the energy limit of each plateaux. In the case of the ferromagnetic interaction the barrier is lowest for the largest possible spin, while in the case of the antiferromagnetic interaction the opposite situation is realized. Now, for the unpolarized initial state, the probabilities of realization of the  $J_T = 3, 2, 1, 0$  configurations of the total spin are 7/16, 5/16, 3/16 and 1/16. Bearing in mind that in the case  $\Delta = 0$  the conductance of non-interacting system

Figure 2: Steps of the quantum conductance staircase vc the chemical potential of carriers in a Si QPC for the antiferromagnetic case. We used the same parameters of Fig.(1), only changing for an antiferromagnetic exchange interaction,  $V_{ex} \simeq 0.5meV$ , and supposing  $V_{dir} \simeq 2meV$ . The vertical gray lines correspond to the values of the heights of the effective potential barriers,  $V_{dir} - 15V_{ex}/4, V_{dir} - 11V_{ex}/4, V_{dir} - 3V_{ex}/4$  and  $V_{dir} + 9V_{ex}/4$ , whereas the dashed horizontal lines correspond to the values  $e^2/4h$ ,  $e^2/h$  and  $9e^2/4h$ .

is quantized in units of  $4e^2/h$ , one easily obtains the values of the fractional conductance of the interacting system mentioned above.

The situation is different if the offset between the bands of light and heavy holes is not negligible. This version is illustrated when  $\Delta \rightarrow \infty$  that should be realized in extremely narrow wires. In this case both localized and propagating carriers are heavy holes, and thus the conductance of non-interacting system is quantized in the units of  $2e^2/h$ . The spins of the pair of holes can be either parallel or antiparallel. Bearing in mind that in the absence of the external magnetic field both configurations have equal probability and spin-flip processes are blocked because of the large offset of the intermediate light hole states, one obtains just one additional plateau in the fractional conductance corresponding to  $G = e^2/h$ . The stiuation is thus different from the case of electrons where spin-flip processes are allowed and additional plateau is formed at  $G = 3e^2/2h^{16}$ .

When  $\Delta$  is finite, it is clearly that the situation is beyond the two considered extreme versions, as it is also illustrated in Figs.(1) and (2). Both probabilities of realization of initial states and transmission amplitudes are seen to be strongly energy dependent.

The quantization of the ballistic conductance associated with holes in Ge and GaAs structures is expected to be qualitatively the same as in Si because of the similarity of the spin structure of the valence band in these materials. However, it can be qualitatively different in IV-VI semiconductors such as PbTe, PbSe and PbS where the electron-hole symmetry holds.

In addition, we also analyzed the effects of an applied external magnetic field parallel to the structure growth axis which produces the Zeeman splitting of the light and heavy hole bands,  $H^{lh,hh} = -g_{\parallel}^{lh,hh} \mu_b J_z^{lh,hh} B$ , where  $\mu_b$  is the Bohr mag-

Figure 3: Effect of an external magnetic field applied along the growth axis of a Si QPC. Except for the applied magnetic field, we used the same parameters of Fig.(1), with  $\Delta = 0.45 meV$ . We see that moderate magnetic fields, B = 1.5T, reduce the relative width of the steps, change their position and increase their number, while stronger ones, B = 3.0T, tend to reduce the effect of the spin effective potential barrier, resulting in steps at integer values of the quantum conductance. The values of the effective potential barriers appear as vertical gray lines, while the energies of the bottom of the subbands, appear as vertical dotted lines. Observe that there is an inversion between the light and heavy hole subbands because of the difference in their effective g-factor and the strong magnetic field.

neton and  $g_{\parallel}^{lh,hh}$  are the parallel components of the effective g-factors tensors of the light and heavy holes subbands. In our calculations for Si QPCs, we estimate the g-factors as the ones of the bulk Si,  $g_{\parallel}^{lh} = 2\kappa$  and  $g_{\parallel}^{hh} = 6\kappa$ , with the Luttinger parameter  $\kappa = -3.41^{23}$ . So, the propagating and localized light and heavy hole subbands will be split with the energies  $\Delta_Z^{lh} = 2\kappa\mu_b B$  and  $\Delta_Z^{hh} = 18\kappa\mu_b B$ , respectively. In this case we

do not have invariance as respect to the spin inversion and the conductance of the system will be given by the sum of all distinct 44 transmissions amplitudes present in eq.(2). The results of our calculation are summarized in Fig.(3). The Zeeman splitting in each of the light and heavy hole subbands, in addition to the  $\Delta$  splitting between them, increases the energy dependence of the initial state's probabilities of realization and of the scattering processes. Therefore, under a moderate magnetic field, the relative width of the steps in the quantum conductance tends to be reduced, increasing in number and changing in energy. This behavior is illustrated by the plotted conductance for B = 1.5T in Fig.(3). However, if the external magnetic field is strong enough such that the heights of the spin effective potential barrier are smaller than the splitting between the different subbands, then the conductance of the system tends to show plateaux at the integer values of  $e^2/h$ . In the case of B = 3.0T, in Fig.(3), the plateaux at  $e^2/h$  and  $3e^2/h$  are very clear, while the plateau at  $2e^2/h$  is absent, because the spliting between the second and third subbands is smaller than the heights of the spin effective potential barriers.

In conclusion, we have considered the effect of the exchange interaction on the fractional quantization of the ballistic conductance of the hole systems. It results in the fractional quantization of the ballistic conductance different from those in electronic systems. The value of the conductance at the additional plateaux depends on the offset between the bands of the light and heavy holes  $\Delta$ , the sign of the exchange interaction constant and external magnetic field.
