Abstract

We review recently developed two-step approach for description of electronic and magnetic properties of a new class of materials, the diluted magnetic semiconductors. In the first step we construct, on the basis of the state-of-the-art first-principles electronic structure calculations, the effective Ising and Heisenberg Hamiltonians which describe, respectively, the alloy phase stability and the magnetic excitations in the system. In the second step, we analyze properties of these effective Hamiltonians by various methods of statistical physics. As a case study, the prototypical diluted magnetic semiconductor $Ga_{1-x}Mn_xAs$ is studied in detail. We determine, among others, a possibility for clustering in this system, formation energies of various compensating defects, and estimate short-range order parameters describing ordering tendencies in a system. On the other hand, by using recently developed local random-phase approximation approach, we evaluate the system Curie temperature and demonstrate its strong dependence on the sample preparation. We also emphasize the relevance of proper inclusion of the randomness in positions of magnetic impurities for a reliable estimate of the system critical temperature. Finally, we compare calculated Curie temperatures with available experimental data and briefly mention relation to other theoretical approaches.

I. INTRODUCTION

Properties of semiconductors are very sensitive to a small amount of various impurities and defects while magnetism is a collective phenomenon often stable to high temperatures. Magnetic order in the system strongly influences other material properties, like e.g., the phase stability, and transport and optical properties. Also, unique properties of both semiconductors and magnetic materials form basis of many important technologies. The combination of properties of both these classes of materials seems to be very promising and in fact resulted recently [1] into the discovery of a new class of materials, the diluted magnetic semiconductors (DMS), of which the diluted III-V DMS is the best example and (Ga,Mn)As system is the most frequently studied one both experimentally and theoretically.

In addition to being promising in future spintronics applications, the DMS represent also the challenge to the solid state and material science physics. A main feature of these new materials is ferromagnetism which is primarily due to coupling of impurity magnetic moments mediated by free carriers, typically by holes, in the host semiconductor valence band. These holes are introduced into the GaAs host by Mn-impurities but their concentration in the system can be strongly influenced by the presence of native defects, namely by Asantisites on the Ga-sublattice and by Mn-interstitials. The hybridization between magnetic impurity and host electronic states leads to a formation of virtual bound states for which proper inclusion of electron correlations can be quite important. However, one of the most important features characterizing the DMS is the presence of the disorder and, in particular, how the disorder influences the distribution of magnetic and other impurities: the atom clustering or segregation, the tendency of foreign atoms to be incorporated into the system in the presence of other impurities, both native and doping ones, etc. are relevant questions to be addressed. In addition to these basic structural issues there is an equally important question of how important can be disorder for the Curie temperature of the system: sufficiently robust ferromagnetism is a key point for any future technological application of the DMS.

There is an extensive literature on the theory of DMS [2, 3, 4] which, however, summarizes mostly results of model approach to the problem. The parameter-free, first-principles studies are less frequent and a systematic, comprehensive review on this subject is still missing. The aim of this paper is not to give such a review but rather to illustrate one specific approach which employs the first principles calculations as a starting point for the construction of simple, effective Hamiltonians which could address various important problems from the fields of the phase stability and magnetic excitations in a simple, transparent way rather than to attempt to study these problems fully on the first-principle level, which is still in most cases numerically prohibitive. Below we will consider two such models, the Ising and Heisenberg Hamiltonians, whose parameters, the effective pair interactions in the former case, and the pair exchange interactions in latter case, are determined on the basis of the same first principles calculations. In both cases such parameters can be determined either from *ad hoc* chosen structural or magnetic configurations in the framework of conventional, electronic structure supercell calculations [5, 6] or, as in the present case, by explicitly including the effect of disorder in terms of the coherent-potential approximation (CPA) [7]. One obvious advantage of the present approach is the possibility to include the effect of small concentrations of various types of impurities as well as the effect of finite lifetime due to disorder, features typical for the DMS, on the same footing. On the other hand, the effect of clustering on the electronic and magnetic structure can be more straightforwardly included using the supercell approach. A detailed comparison of both approaches is, however, beyond the scope of the present paper. An emphasis will be put on the study of magnetic properties of GaMnAs alloys, in particular on the determination of their Curie temperatures based on a detailed study of the corresponding Heisenberg Hamiltonian by sophisticated statistical methods which take into account both random positions of Mn-impurities and the presence of compensating defects in a system.

II. ELECTRONIC STRUCTURE

We have determined the electronic structure of the DMS in the framework of the first principles all-electron tight-binding linear muffin-tin orbital (TB-LMTO) method in the atomic-sphere approximation using empty spheres in interstitial tetrahedral positions of the zinc-blende lattice for a good space filling. We used equal Wigner-Seitz radii for all atoms and empty spheres. The valence basis consists of s-, p-, and d-orbitals, we include scalarrelativistic corrections but neglect the spin-orbit effects. The substitutional disorder due to Mn-atoms and other possible defects is included within the CPA. The charge selfconsistency is treated in the framework of the local spin density approximation using Vosko-Wilk-Nusair parameterization for the exchange-correlation potential [8]. The lattice constant of the pure GaAs (a = 5.653 Å) was used in all calculations but we have verified that we can neglect a weak dependence of the sample volume on defect concentrations. Further details of the method can be found in [7].

The magnetic disorder is treated in the framework of the disordered local moment (DLM) method [9] which is the simplest way of including disorder in spin orientations and which is justified for atoms with large exchange splitting. A comparison of the total energies of the ferromagnetic (FM) state with its DLM counterpart is the simplest way to investigate the magnetic stability of the DMS alloy [10, 11]. In addition, the DLM is a natural starting point for the phase stability studies due to the fact that sample preparation is done at temperatures well above the system Curie temperature. The DLM can be included in the framework of the CPA: the Mn atoms have collinear but random positive (Mn^+) and negative (Mn⁻) orientations with corresponding concentrations x^+ and x^- , $x = x^+ + x^-$, where x is the total Mn-concentration. The degree of magnetic order can then be characterized by the order parameter $r = (x^+ - x^-)/x$, and $x^{\pm} = (1 \pm r)x/2$. In the (FM) state, r = 1, all magnetic moments are aligned in the direction of a global magnetization. The non-magnetic state, r = 0, is characterized by a complete disorder of spin directions with vanishing total magnetization while a partial ferromagnetic state is characterized by 0 < r < 1. For more details concerning the determination of the magnetic phase diagram and magnetic moments in different magnetic states we refer to [12, 13].

In Fig. 1 we plot the local density of states on Mn-atoms, clearly illustrating general features of the GaMnAs alloys which will be relevant for their magnetic properties: (i) the halfmetallic character of spin-subbands with a gap in the minority states, and (ii) the strong disorder introduced by the presence of Mn-impurities in the GaAs host as manifested by its pronounced difference from the host GaAs density of states. Also the reference host bandstructure is shown for an illustration.

III. ISING HAMILTONIAN OF AN ALLOY

Some important problems concerning the structure and phase stability of DMS can be studied on the basis of the Ising Hamiltonian describing various configurations of disordered alloys with parameters determined from first principles. A particular configuration of a

FIG. 1: Electronic structure of $(Ga_{0.05}, Mn_{0.05})$ As random alloy. The upper and lower insets show the total density of states and the bandstructure along principal axis in the Brillouin zone of the host GaAs crystal. The spin-polarized local density of states on Mn-atoms substituting cations on Ga-sublattice is shown in the main frame.

homogeneous disordered multicomponent alloy is characterized by occupation indices $\eta_{\mathbf{R}}^Q$, where $\eta_{\mathbf{R}}^Q = 1$ if the site \mathbf{R} is occupied by an atom of type Q, and $\eta_{\mathbf{R}}^Q = 0$ otherwise. Configurational averaging of occupation indices $\langle \eta_{\mathbf{R}}^Q \rangle = c^Q$ yields the concentrations c^Q . The configurationally dependent part of the alloy internal energy is given by the effective Ising Hamiltonian

$$H = +\frac{1}{2} \sum_{\mathbf{RR}'} \sum_{QQ'} V_{\mathbf{RR}'}^{QQ'} \eta_{\mathbf{R}}^{Q} \eta_{\mathbf{R}'}^{Q'} + \dots , \qquad (1)$$

where $V_{\mathbf{RR}'}^{QQ'}$ are interatomic pair interactions. Here we will not consider higher order interactions.

The pair interactions $V^{QQ'}_{\mathbf{RR'}}$ in DMSs consist of two contributions,

$$V_{\mathbf{R}\mathbf{R}'}^{QQ'} = v_{\mathbf{R}\mathbf{R}'}^{QQ'} + \phi_{\mathbf{R}\mathbf{R}'}^{QQ'} , \qquad (2)$$

where the $v_{\mathbf{RR}'}^{QQ'}$ result from mapping of the band part of the total energy onto the Ising Hamiltonian (1) and the $\phi_{\mathbf{RR}'}^{QQ'}$ represent the electrostatic interaction energy of a pair of atoms Q, Q' located at sites \mathbf{R}, \mathbf{R}' (for derivation see Appendix A in [14]) $\phi_{\mathbf{RR}'}^{QQ'} = e^2 q_{\text{eff}}^Q q_{\text{eff}}^{Q'} / |\mathbf{R} - \mathbf{R}'|$, where $q_{\text{eff}}^Q = q^Q - \bar{q}$ is the effective net charge of atomic species Q defined as a difference of the net charge q^Q of atomic species Q and the averaged charge \bar{q} . The band term contribution is calculated using the Generalized Perturbation Method (GPM)[5, 7, 15]

$$v_{\mathbf{R}\mathbf{R}'}^{QQ'} = \frac{1}{\pi} \operatorname{Im} \int_{E_{\min}}^{E_{\mathrm{F}}} \mathrm{d}E \operatorname{tr} \left[t_{\mathbf{R}}^{Q}(z) \bar{g}_{\mathbf{R}\mathbf{R}'}(z) t_{\mathbf{R}'}^{Q'}(z) \bar{g}_{\mathbf{R}'\mathbf{R}}(z) \right],$$
(3)

where tr denotes a trace over angular momentum indices (ℓm) and the spin index σ , z = E+i0, $E_{\rm F}$ is the CPA Fermi energy, $E_{\rm min}$ is a suitably chosen energy below the valence energy spectrum, $\bar{g}_{{\bf R}{\bf R}'}(z)$ denotes the block of the averaged auxiliary Green function between sites **R** and **R'**, and $t^Q_{\bf R}(z)$ is the t-matrix for atomic species Q.

A. Impurity formation energies

The calculated total energies (per elementary cell) make possible to investigate impurity formation energies for DMSs. The formation energy $\varepsilon[A_B]$ of an impurity A_B which substitutes a host atom B in a (generally multicomponent) alloy $A_x B_{1-x}$ is defined as

$$\varepsilon[\mathbf{A}_{\mathbf{B}}] = NE[\mathbf{A}_{x+\delta x}\mathbf{B}_{1-x-\delta x}] + E_{\mathrm{at}}[B] - \{NE[\mathbf{A}_{x}\mathbf{B}_{1-x}] + E_{\mathrm{at}}[A]\},$$
(4)

where N is the number of elementary cells in the alloy, $\delta x = 1/N$, $E_{\text{at}}[A]$ is the energy of an isolated atom A, and $E[A_x B_{1-x}]$ is the energy of the alloy per one elementary cell. By expanding into linear terms in δx one finds [16]

$$\varepsilon[\mathbf{A}_{\mathrm{B}}] = \frac{\partial E[\mathbf{A}_{x}\mathbf{B}_{1-x}]}{\partial x} + E_{\mathrm{at}}[B] - E_{\mathrm{at}}[A].$$
(5)

Our calculations [14] for $(Ga_{1-x-y}Mn_xAs_y)As$ alloys have shown that the formation energy of As antisite defect decreases with increasing concentration x of substitutional Mn atoms, which means that the number of the antisite defects can be considerably enhanced in the presence of substitutional Mn. Similarly, the formation energy of the substitutional Mn decreases with an increasing concentration y of As antisites. This means that the presence of As antisites (and probably also of other donors [16]) is important for an improved solubility of Mn in III-V materials. The behavior of formation energies for interstitial Mn impurities and for As antisites in the presence of interstitials is opposite to that found for substitutional Mn because increasing concentration of one of the species leads to a growth of the impurity formation energy of the other one. This is in agreement with the growth mechanism of $(Ga_{1-x-y}Mn_xAs_y)As$ alloys discussed by Erwin and Petukhov [17]: the Mn atoms are first incorporated into interstitial positions under low concentration of As antisites, and later on, during growth or annealing, as substitutional impurities. In particular, the conversion of the interstitial Mn into a substitutional form is facilitated during the growth process if a sufficient number of As antisites is available. Both discussed mechanisms contribute to the self-compensation behavior of as-grown (Ga,Mn)As alloys.

B. Alloy stability

The calculated total energies (per elementary cell) make possible to investigate the stability of DMSs with respect to segregation into systems with different chemical composition. For example, consider segregation of $(Ga_{1-x-y}Mn_xAs_y)As$ into an alloy without As-antisites $(Ga_{1-x}Mn_x)As$ and an alloy with the highest possible concentration of As-antisites which is still not overcompensated, $(Ga_{1-3x/2}Mn_xAs_{x/2})As$,

$$\Delta E(x,y) = E[(\operatorname{Ga}_{1-x-y}\operatorname{Mn}_{x}\operatorname{As}_{y})\operatorname{As}] - \frac{x-2y}{x}E[(\operatorname{Ga}_{1-x}\operatorname{Mn}_{x})\operatorname{As}] - \frac{2y}{x}E[(\operatorname{Ga}_{1-3x/2}\operatorname{Mn}_{x}\operatorname{As}_{x/2})\operatorname{As}].$$
(6)

The energy $\Delta E(x, y)$ is negative [14] which indicates the stabilizing effect of the As antisites. This is in agreement with the above conclusions based on the impurity formation energies.

Similarly, we can consider segregation of the alloy $(Ga_{1-x}Mn_x)As$ into pure GaAs and an alloy with higher concentration of Mn atoms, say x_0 , $(Ga_{1-x_0}Mn_{x_0})As$,

$$\Delta E(x, x_0) = E[(\operatorname{Ga}_{1-x}\operatorname{Mn}_x)\operatorname{As}] - \frac{x_0 - x}{x_0} E[\operatorname{GaAs}] - \frac{x}{x_0} E[(\operatorname{Ga}_{1-x_0}\operatorname{Mn}_{x_0})\operatorname{As}].$$
(7)

Our calculations [14] have shown that this energy is positive which shows that the alloy $(Ga_{1-x}Mn_x)As$ is thermodynamically unstable with respect to segregation.

C. Ordering tendencies

The effective interatomic pair interactions $V_{\mathbf{RR'}}^{QQ'}$ in semiconductors decrease rather slowly with the interatomic distance $|\mathbf{R} - \mathbf{R'}|$ and have to be calculated over many coordination spheres [14]. Also their Coulombic part, even though weak, is long-ranged. In order to analyze possible ordering patterns, we employed the linearized concentration wave method and for temperatures above the ordering temperature T_{ord} we also calculated Warren-Cowley short-range order parameters. One has to keep in mind that in these methods only the configurational part of the entropy is taken into account which usually leads to an overestimation of ordering temperatures.

The ordering temperature T_{ord} and the type of ordered structure that appears below T_{ord} can be studied in terms of the concentration-wave method [5, 18]. Here we employ its linearized version [19] extended to a multicomponent alloy since we consider possible ordering of four atomic species (Ga, Mn[↑], Mn[↓], As) on the cation sublattice. In a mean field approximation (i.e., assuming a Bragg-Williams form of the entropy [20]) the free energy is expressed in terms of local concentrations $c_{\mathbf{R}}^Q$,

$$F = \frac{1}{2} \sum_{\mathbf{R}\mathbf{R}'} \sum_{QQ'} V_{\mathbf{R}\mathbf{R}'}^{QQ'} c_{\mathbf{R}}^{Q} c_{\mathbf{R}'}^{Q'} + k_{\mathrm{B}} T \sum_{\mathbf{R}} \sum_{Q} c_{\mathbf{R}}^{Q} \ln(c_{\mathbf{R}}^{Q}), \qquad (8)$$

where $k_{\rm B}$ is the Boltzmann constant and T is the temperature. Starting from the disordered state, the free energy can be expanded up to quadratic terms in concentration fluctuations $\delta c_{\mathbf{R}}^{Q} = c_{\mathbf{R}}^{Q} - c^{Q}$,

$$F = F_0 + \frac{1}{2} \sum_{\mathbf{RR}'} \sum_{QQ'} \left[V_{\mathbf{RR}'}^{QQ'} + \frac{k_{\mathrm{B}}T}{c^Q} \delta_{\mathbf{RR}'} \delta_{QQ'} \right] \delta c_{\mathbf{R}}^Q \, \delta c_{\mathbf{R}'}^{Q'} \tag{9}$$

with terms linear in $\delta c_{\mathbf{R}}^{Q}$ vanishing because $\sum_{\mathbf{R}} \delta c_{\mathbf{R}}^{Q} = 0$ for all Q, and $\sum_{\mathbf{R}'Q'} V_{\mathbf{RR}'}^{QQ'} c^{Q'}$ is a constant for all \mathbf{R} and Q (for details see Ref. [19]). Here F_0 is the free energy in the absence of concentration waves ($c_{\mathbf{R}}^{Q} = c^{Q}$ for all \mathbf{R}). Equation (9) can be rewritten in terms of a lattice Fourier transform in a matrix notation as

$$\Delta F = F - F_0 = \frac{1}{2} \sum_{\mathbf{k}}^{\mathrm{BZ}} Y^{\dagger}(\mathbf{k}) \Big[V(\mathbf{k}) + k_{\mathrm{B}} T C^{-1} \Big] Y(\mathbf{k}) |\epsilon(\mathbf{k})|^2 , \qquad (10)$$

where $[V(\mathbf{k})]_{QQ'} = V^{QQ'}(\mathbf{k})$, and the matrix C is defined as $[C]_{QQ'} = c^Q \delta_{QQ'}$. In Eq. (10) the concentration fluctuations $\delta c^Q(\mathbf{k})$ are expressed in terms of a vector $Y(\mathbf{k})$ and the order parameter $\epsilon(\mathbf{k})$ as $\delta c^Q(\mathbf{k}) = Y^Q(\mathbf{k})\epsilon(\mathbf{k})$. At sufficiently high temperatures ΔF is positive definite, because the hermitian matrix $V(\mathbf{k}) + k_{\rm B}TC^{-1}$ has only positive eigenvalues and thus the high temperature state is completely disordered ($\epsilon(\mathbf{k}) = 0$ for all \mathbf{k}). With decreasing temperature it can become indefinite at $T_{\rm ord}$ because of a vanishing eigenvalue for a critical vector \mathbf{k}_0 which determines the period of the concentration wave. The components $Y^Q(\mathbf{k})$ of the critical eigenvector determine the amplitude of the concentration wave for each alloy component Q. For each \mathbf{k} , the minimization of ΔF , and thus the eigenvalue problem, is subject to the subsidiary condition $\sum_Q Y^Q(\mathbf{k}) = 0$ which follows from $\sum_Q \delta c_{\mathbf{R}}^Q = 0$, valid for each \mathbf{R} . The ordering temperature is then found as the largest eigenvalue of the matrix $\Theta(\mathbf{k}) = -k_{\rm B}^{-1}C^{\frac{1}{2}}V(\mathbf{k})C^{\frac{1}{2}}$.

For example, for a ferromagnetic alloy $(\text{Ga}_{0.93}\text{Mn}_{0.06}^{\uparrow}\text{As}_{0.01})$ As we found [14] the ordering temperature $T_{\text{ord}} = 775$ K and the ordering vector $\mathbf{k}_0 = 0.274(1,1,1)/a$, where *a* is the lattice constant. A closer examination shows that the largest eigenvalues of the matrix $\Theta(\mathbf{k})$ have very similar values (within 1 K) for **k**-vectors close to a surface of a sphere of radius 0.479/a, which corresponds to a domain of a characteristic radius 3.7 nm in real space. The components of the eigenvector $Y(\mathbf{k}_0)$ are Y(Ga) = 0.726, $Y(\text{Mn}^{\uparrow}) = -0.686$, and Y(As) = -0.040, which corresponds to formation of domains of two types: in the first type the concentration of impurities Mn and As is increased, while in the second type the impurity concentrations are diminished in agreement with the above estimate based on the segregation energy (7).

D. Short-range order parameters

The Warren-Cowley short-range order parameters [5]

$$\alpha_{\mathbf{R}\mathbf{R}'}^{QQ'} = -\frac{\langle \eta_{\mathbf{R}}^{Q} \eta_{\mathbf{R}'}^{Q'} \rangle - \langle \eta_{\mathbf{R}}^{Q} \rangle \langle \eta_{\mathbf{R}'}^{Q'} \rangle}{\langle \eta_{\mathbf{R}}^{Q} \rangle \langle \eta_{\mathbf{R}'}^{Q'} \rangle} = 1 - \frac{\langle \eta_{\mathbf{R}}^{Q} \eta_{\mathbf{R}'}^{Q'} \rangle}{c^{Q} c^{Q'}}$$
(11)

provide detailed information on mutual correlations of impurities; they also can directly be used in calculations of transport and magnetic properties. The matrix of the Warren-Cowley parameters can be approximately calculated by means of the Krivoglaz-Clapp-Moss (KCM) formula in reciprocal space,

$$\alpha(\mathbf{k}) = -D[M + \beta \widetilde{V}(\mathbf{k})]^{-1}D^T, \qquad (12)$$

where $\beta = (k_{\rm B}T)^{-1}$, and the matrix M is defined as $[M]_{QQ'} = 1/c^0 + \delta_{Q,Q'}/c^Q$. The matrix D is introduced to ensure a correct normalization of α for $\mathbf{R} = \mathbf{R}'$ which follows from the

definition in (11). Note that $\widetilde{V}(\mathbf{k})$ is a Fourier transform of $\widetilde{V}_{\mathbf{R}\mathbf{R}'}^{QQ'} = V_{\mathbf{R}\mathbf{R}'}^{QQ'} + V_{\mathbf{R}\mathbf{R}'}^{00} - V_{\mathbf{R}\mathbf{R}'}^{00} - V_{\mathbf{R}\mathbf{R}'}^{0Q'}$, which is the matrix of pair interactions from which one atomic species was eliminated. The inverse lattice Fourier transform of (12) then yields the Warren-Cowley parameters in the real space.

The results for the Warren-Cowley parameters show a strong tendency to an aggregation of Mn atoms with the same orientation of spin. This finding is in line with the results of Ref. [21]. Close pairs of Mn atoms with opposite moments become possible, while the probability to find close pairs of As antisites is very low. A moderate aggregation of Mn atoms and As antisites is also possible.

The results for the Warren-Cowley parameters show a strong tendency to an aggregation of Mn atoms with the same orientation of spin. This finding is in line with the results of Ref. [21]. Close pairs of Mn atoms with opposite moments become possible, while the probability to find close pairs of As antisites is very low. A moderate aggregation of Mn atoms and As antisites is also possible.

E. Conclusions from structural studies

The main conclusions can be summarized as follows:

(i) The alloys are thermodynamically unstable with respect to segregation into related compounds or alloys.

(ii) As-antisites have a stabilizing effect and make the incorporation of substitutional Mn atoms energetically favorable. On the other hand, incorporation of Mn atoms into interstitial positions is energetically favorable only at low concentration of As antisites.

(iii) Formation of domains of two types, namely, with an enhanced and with a lowered concentration of impurities (substitutional Mn atoms and As antisites), can be expected. The characteristic size of the domains depends on chemical composition and might be of order of several nm.

(iv) A strong tendency to aggregation of substitutional Mn atoms with parallel magnetic moments is expected, while the formation of close pairs of As antisites is highly unlikely.

IV. HEISENBERG HAMILTONIAN

The knowledge of exchange interactions allows one to address in detail the character of magnetic excitations in the DMS, i.e., to evaluate the Curie temperature, the spin-wave stiffness, and the spectrum of low-lying magnetic excitations. Magnetic excitations in ferromagnets are of two different kinds, namely, Stoner excitations associated with longitudinal fluctuations of the magnetization, and spin-waves, or magnons corresponding to collective transverse fluctuations of the magnetization direction. The low-temperature regime is dominated by magnons and Stoner excitations can be usually neglected. In this section we will construct an effective random Heisenberg Hamiltonian with classical spins which will be used in the next section to study the critical temperatures. The main idea is to separate a relevant part of (very) small magnetic energies responsible for magnetic ordering from huge total energies obtained from first-principles total energy calculations [22]. The validity of this approach, based on the adiabatic approximation, is in particular justified for magnetic atoms with large exchange splitting, like, e.g., Mn-impurities in GaAs host. The mapping is further simplified by using the magnetic force-theorem [22, 23] which states that the band energy of the calculated ground state of a reference spin structure can be used as an estimate for corresponding total-energy differences in the excited state. Note that intracell non-collinearity of the spin polarization is neglected since in this approach we are primarily interested in low-energy excitations due to intercell non-collinearity. The application of this approach to disordered systems like the DMS is significantly simplified by using the vertex-cancellation theorem (VCT) which justifies the neglect of disorder-induced vertex corrections in Eq. (14) below. The VCT was derived in [24] under rather general conditions and facilitates an efficient evaluation of exchange interactions, exchange stiffnesses, spin-wave energies, etc. The present real-space approach is particularly suitable for random systems with low concentrations of magnetic impurities such as the DMS, where the effect of disorder is treated in the framework of the CPA. It is also possible to estimate exchange interactions from energy differences between parallel and various antiparallel configurations of a few magnetic atoms in a supercell representing specific concentration (the real-space supercell approach) [25]. In this way exchange interactions of magnetic clusters could be estimated approximately. Alternatively, the reciprocal-space approach to the problem is also possible, namely the frozen-magnon method combined with the supercell approach [26].

We refer reader to a recent review [6] for more details, comparison of the real-space and reciprocal-space approaches, as well as for applications of the above formalism to a broad range of various magnetic systems.

A. Effective pair exchange interactions

The mapping of the total energy of itinerant electron system connected with small rigid rotations of two magnetic moments at sites \mathbf{R} and \mathbf{R}' can be described by the effective Heisenberg Hamiltonian with classical spins as discussed above

$$H_{\rm eff} = -\sum_{\mathbf{R}\neq\mathbf{R}'} J_{\mathbf{R},\mathbf{R}'} \mathbf{e}_{\mathbf{R}} \cdot \mathbf{e}_{\mathbf{R}'} \,. \tag{13}$$

Here, $J_{\mathbf{R},\mathbf{R}'}$ is the exchange interaction energy between sites (\mathbf{R},\mathbf{R}') , and $\mathbf{e}_{\mathbf{R}},\mathbf{e}_{\mathbf{R}'}$ are unit vectors pointing in directions of local magnetic moments at sites (\mathbf{R},\mathbf{R}') , respectively. In the present formulation the values and signs of the magnetic moments are already absorbed in the definition of the $J_{\mathbf{R},\mathbf{R}'}$'s so that positive (negative) $J_{\mathbf{R},\mathbf{R}'}$'s correspond to ferromagnetic (antiferromagnetic) coupling. By adopting the magnetic force-theorem [6, 22, 23], the configurationally averaged effective pair exchange interactions $\bar{J}_{\mathbf{R},\mathbf{R}'}^{M,M'}$ between two magnetic atoms M, M' located randomly at sites \mathbf{R} and \mathbf{R}' are given by the following expression [11]:

$$\bar{J}^{M,M'}_{\mathbf{R},\mathbf{R}'} = \frac{1}{4\pi} \operatorname{Im} \int_{C} \operatorname{tr}_{L} \left[\delta^{M}_{\mathbf{R}}(z) \, \bar{g}^{M,M'\uparrow}_{\mathbf{R},\mathbf{R}'}(z) \, \delta^{M'}_{\mathbf{R}'}(z) \, \bar{g}^{M',M\downarrow}_{\mathbf{R},\mathbf{R}}(z) \right] \mathrm{d}z \,. \tag{14}$$

Here, tr_L denotes the trace over angular momenta $L = (\ell m)$, the energy integration is performed in the upper half of the complex energy plane along a contour C starting below the bottom of the valence band and ending at the Fermi energy, and $\delta^M_{\mathbf{R}}(z) = P^{M,\uparrow}_{\mathbf{R}}(z) - P^{M,\downarrow}_{\mathbf{R}}(z)$, where the $P^{M,\sigma}_{\mathbf{R}}(z)$ are the L-diagonal matrices of potential functions of the TB-LMTO method for $\sigma =\uparrow,\downarrow$ corresponding to a particular magnetic atom M. The matrix $\delta^M_{\mathbf{R}}(z)$ reflects the exchange splitting of atom M. The quantities $\bar{g}^{M,M'\uparrow}_{\mathbf{R},\mathbf{R}'}(z)$ and $\bar{g}^{M',M\downarrow}_{\mathbf{R}',\mathbf{R}}(z)$ refer to site off-diagonal blocks of the conditionally averaged Green function [7], namely, the average of the Green function over all configurations with atoms of the types M and M' fixed at sites \mathbf{R} and \mathbf{R}' , respectively, determined in the framework of the CPA [7]. The exchange interactions between magnetic moments induced on non-magnetic atoms are negligible as compared to the exchange interactions between magnetic atoms in the present case, i.e., M=M'=Mn in (Ga,Mn)As alloys. The main advantage of the present approach is the explicit expression for $\bar{J}_{\mathbf{R},\mathbf{R}'}^{M,M}$ which can be evaluated straightforwardly even for large distances $d = |\mathbf{R} - \mathbf{R}|$ between sites \mathbf{R} and $\mathbf{R'}$ and thus allowing the study of their asymptotic behavior as a function of the interatomic distance d [6, 11]. It should be noted that the rigidity of spins during rotations as required by the Heisenberg model is preserved by construction in the present approach and in the reciprocal-space method [26] but not in the real-space supercell approach [25].

The effect of impurities on the host bandstructure is usually neglected in model theories [2, 3], but it need not be a small perturbation in the presence of the virtual-bound states [27]. It is also relevant for DMS systems as it was demonstrated recently [28] by using the selfconsistent local RPA theory [29]: the combined effect of random geometry and thermal fluctuations is crucial and calls for a proper treatment. In particular, it was shown that damped RKKY interactions often used in model studies, are unable to represent properly the effect of virtual bound states in the host band on the values of exchange interactions, and corrections are needed (see also [30]). The standard RKKY exchange interactions cannot explain ferromagnetism observed in the DMS: one has to go further in this perturbation scheme to include properly effects of resonances due to virtual bound states. On the other hand as already mentioned, in the present approach is the effect of virtual bound states included by construction.

The neglect of the effect of impurities on exchange interactions means that the unperturbed host Green function appears in (14) rather than its conditionally averaged counterpart $\bar{g}_{\mathbf{R},\mathbf{R}'}^{M,M'\sigma}(z)$. The neglect of the renormalization of the host Green function by scatterings on impurities is two-fold: it introduces a phase factor and modifies the amplitude of the oscillations as compared to the conventional RKKY formula [31].

The present approach neglects the effect of local environment effects: while the individual $J_{\mathbf{R},\mathbf{R}'}^{M,M}$ can be very different for a particular environment, the corresponding configurationally averaged $\bar{J}_{\mathbf{R},\mathbf{R}'}^{M,M}$ in random systems are close to the CPA value, Eq. (14), as demonstrated recently [32]. The CPA also correctly describes the concentration trends and the carrier concentrations which, in turn, determine the size of the alloy Fermi surface and thus the periods of oscillations. The exchange interactions in GaMnAs alloys are exponentially damped due to the alloy disorder and by their halfmetallic character as illustrated in Fig. 2 below. The exchange interactions are also strongly anisotropic in the real space due to the underlying zinc-blende lattice while an additional, but weaker anisotropy, could be due to the neglected

FIG. 2: Exchange interactions $J^{\text{Mn,Mn}}$ between pairs of Mn atoms in $(\text{Ga}_{0.95-y}, \text{Mn}_{0.05}, \text{As}_y)$ As alloy plotted as a function of their interatomic distance d (in units of the lattice constant a). Full and empty symbols correspond to y = 0 and y = 0.01, respectively, where y is the concentration of As-antisites on the Ga-sublattice. In the inset we show $\ln|(d/a)^3 J^{\text{Mn,Mn}}(d)|$ as a function of the interatomic distance d along the [110]-direction with dominating values of exchange interactions.

spin-orbit effects. Finally, because the hybridization between Mn- and host-atoms is included by construction to all orders, both the RKKY-like and superexchange interactions are included in the theory although their separation is not possible in a simple way.

The typical results for exchange interactions in (Ga,Mn)As alloys are illustrated in Fig. 2. We observe well pronounced ferromagnetic behavior of GaAs semiconductor doped with 5% of Mn-impurities: exchange interactions between pairs of Mn atoms, $J^{\text{Mn,Mn}}$, are ferromagnetic over number of nearest neighbors with the dominating first nearest-neighbor interactions $J_1^{\text{Mn,Mn}}$ but without standard RKKY-oscillations. Interactions are strongly reduced by the presence of native As-antisite defects, which reduce the number of free carriers: while each Mn-impurity introduces one hole into the host valence band, the As-antisite (and similarly, the Mn-interstitial) introduces two electrons. With increasing concentration of As-antisites the leading $J_1^{\text{Mn,Mn}}$ becomes negative (antiferromagnetic) and such frustration coincides with the extinction of the ferromagnetism in the system (see below). The damping of exchange interactions due to alloy disorder and, most importantly, due to halfmetallic behavior of GaMnAs alloy, is illustrated in the inset of Fig. 2: the linear decrease of amplitudes of the logarithm of exchange interactions multiplied by the RKKY-like factor $(\ln|(d/a)^3 J^{\text{Mn,Mn}}|)$, indicating their exponential damping for large interatomic distances, is obvious.

B. Curie temperatures of diluted (Ga,Mn)As alloys

Here we briefly describe new approach for a quantitative determination of the Curie temperature T_c which correctly takes into account the randomness in positions of magnetic impurities as well the presence of native defects, like As-antisites and Mn-interstitials and thus allows to explain their role in real samples. The novel feature as compared to the conventional magnet thermodynamics is the dilution, i.e., the presence of randomly distributed magnetic defects of low, but finite concentration leading to the effect of magnetic percolation. It was clearly demonstrated recently [33] that a sophisticated treatment of spin fluctuations using the RPA or Monte-Carlo methods but without inclusion of disorder is itself unable to explain experimentally observed Curie temperatures in the framework of the parameter-free approach: calculated critical temperatures are too high as compared to the experiment. Recently, few groups have formulated parameter-free approaches which take into account properly both disorder and spin-fluctuations and arrived at a fair agreement with experiment for both well-annealed [29, 34, 35, 36, 37] and as-grown samples [39].

The present accurate semi-analytical method separates the exact treatment of disorder and the RPA treatment of spin-fluctuations and has three stages: (i) the first-principle determination of exchange parameters of random classical Heisenberg model [11]; (ii) generation of a sequence of random configurations on a disordered lattice (fcc Ga-sublattice for (Ga,Mn)As alloys) by MC sampling technique; and (iii) for each configuration the random Heisenberg model is treated analytically within the RPA. As the lattice is random, the equations have to be solved numerically.

In the third step, the Green function $G_{\mathbf{R},\mathbf{R}'}$ for impurity spins at sites \mathbf{R} and \mathbf{R}' satisfies

$$(E - h_{\mathbf{R}}^{\text{eff}}) G_{\mathbf{R},\mathbf{R}'}(E) = 2\langle e_{\mathbf{R}}^{z} \rangle \delta_{\mathbf{R},\mathbf{R}'} - \langle e_{\mathbf{R}}^{z} \rangle \sum_{\mathbf{R}''} J_{\mathbf{R},\mathbf{R}''} G_{\mathbf{R}'',\mathbf{R}'}(E),$$

$$h_{\mathbf{R}}^{\text{eff}} = \sum_{\mathbf{R}''} J_{\mathbf{R},\mathbf{R}''} \langle e_{\mathbf{R}}^{z} \rangle.$$
(15)

The quantity $h_{\mathbf{R}}^{\text{eff}}$ is the local effective field acting on the spin at the site \mathbf{R} , and $\langle e_{\mathbf{R}}^{z} \rangle$ is the local magnetic moment at the site \mathbf{R} normalized with respect to the magnetization averaged over all impurities. For a given temperature, $G_{\mathbf{R},\mathbf{R}'}(E)$ for impurity spins are determined following the procedure similar to that of Callen [38] resulting in the selfconsistent solution of the following set of equations for the Curie temperature (for more details see paper [39])

$$k_B T_c = \frac{1}{3N_{\rm imp}} \sum_{\mathbf{R}} \frac{1}{F_{\mathbf{R}}}, \qquad F_{\mathbf{R}} = \int_{-\infty}^{\infty} \frac{A_{\mathbf{R},\mathbf{R}}(E)}{E} dE,$$
$$A_{\mathbf{R},\mathbf{R}}(E) = -\frac{1}{2\pi} \operatorname{Im} \frac{G_{\mathbf{R},\mathbf{R}}(E)}{\lambda_{\mathbf{R}}}, \qquad \lambda_{\mathbf{R}} = \lim_{T \to T_c} \left\langle e_{\mathbf{R}}^z \right\rangle / \bar{e}^z, \qquad (16)$$

where $N_{\rm imp}$ is the number of impurity sites and \bar{e}^z denotes the averaged value of $e_{\mathbf{R}}^z$ over all impurity sites. At the end, the average over typically few hundred configurations of the system, each of them including a few hundredth of impurity sites were enough to give robust values of the Curie temperature (with a numerical accuracy of about few K). On the contrary, the MFA value as evaluated of the average lattice which neglects the randomness in positions of magnetic ions is simply $k_B T_c^{\rm MFA} = (2x/3) \sum_{\mathbf{R}} J_{\mathbf{0},\mathbf{R}}$, where x denotes the concentration of magnetic-atoms [11].

The calculated T_c according Eqs. (16) are shown in Fig. 3 for the case of fully-annealed (Ga,Mn)As samples without native defects (uncompensated samples) and with essentially random distribution of Mn-atoms [29]. In the same Figure we also show experimental results of Edmonds et al. [40], Matsukura [41], and Chiba [42]. The agreement between theory and experiment is very good, except for the single highest concentration (9%). Our calculations thus suggests that for this specific concentration the annealing is complete. The present results are in a good agreement with related studies [34, 37] based on Monte-Carlo simulations used for the treatment of both spin-fluctuations and disorder: the use of the same exchange parameters gives for 5 % 137 K as compared to the value of 125 K in the present approach. Related approach which is based on the Korringa-Kohn-Rostoker (KKR) Green functions developed in [35] gives 103 K. The present theory also correctly predicts an expected threshold (about 1.5%) below which there is no ferromagnetism. It should be noted that the theoretical threshold for the occurrence of magnetism on the fcc lattice and the first nearest-neighbor Heisenberg model (19%) was also confirmed by numerical studies [35, 37]. The calculated realistic exchange interactions, however, extends over several neighbor shells which reduces the effect of magnetic percolation in realistic alloys. On the other hand for

FIG. 3: Calculated Curie temperatures for $(Ga_{1-x} Mn_x)As$ alloys as a function of Mnconcentration. Theoretical results are compared with available experimental data for both well annealed and as-grown samples.

as-grown samples [1, 40] the Curie temperature is significantly reduced by native defects.

An immediate question is what is the proportion of two such defects, Mn-interstitials and As-antisites in as-grown samples. In order to answer this question we have first investigated the effect of As-antisites. The results are presented in Fig. 4. clearly showing a weak dependence of Curie temperatures on the effective carrier concentration γ . First, we observe ferromagnetic instabilities for smaller values of γ . The reason for such instabilities is that for decreasing carrier concentrations are exchange interactions increasingly dominated by the antiferromagnetic (superexchange) contribution leading to a frustration. The experiment [40] for as-grown samples with a nominal Mn-concentration of x = 0.067 shows, however, no ferromagnetic instability. Second, relatively very weak dependence of calculated T_c on γ contradicts experiment which, on the contrary, shows a pronounced dependence on the carrier concentration [40]. These facts seem to exclude As-antisites as a dominating mechanism for compensation in as-grown samples.

We will now demonstrate that observed Curie temperatures of unannealed or compensated samples can be explained assuming that interstitials defects dominate [39]. Such a

FIG. 4: The dependence of calculated Curie temperatures for $(Ga_{1-x-y} Mn_x As_y)As$ alloys for three different Mn-concentrations and for varying concentrations y of As-antisites on Ga-sublattice plotted as a function of the carrier density. The parameter γ is the ratio of the carrier concentration $n_h = x - 2y$ and Mn-concentration x.

dominance agrees with experimental observation of Wolos *et al.* [43] and Wang [44]. We emphasize that a clear proof of the role of interstitials is still necessary as other techniques like transmission electron micrography [45] or infrared absorption and positron annihilation [46] seem to indicate a much higher concentration of antisites. On the other hand, recent theoretical study of Wu [47] also seems to support the model of as-grown alloys described below. The relevant quantity is the compensation parameter $\gamma = n_h/x_{\rm Mn}$, where n_h is the carrier density and $x_{\rm Mn}$ is the nominal concentration of Mn-atoms. It should be noted that both γ and $x_{\rm Mn}$ are available from the experiment [40].

Recent first-principle calculations [48] and Rutherford backscattering experiments [49] indicate that Mn-interstitials (Mn_I) are preferably attracted Mn-substitutional atoms on Ga-sublattice (Mn_{Ga}) forming pairs of spins with a strongly antiferromagnetic coupling. We assume that Mn_I are not completely random but form, with a high accuracy, bound singlet pairs whose effect on magnetically active ions is very small. The remaining active Mn-atoms with effective concentration $x_{\text{eff}} = x_{\text{Mn(Ga)}} - 2x_{\text{Mn(I)}}$ which are not directly coupled to interstitials are assumed to be distributed randomly and interact via the effective

FIG. 5: Curie temperatures of GaMnAs alloys as a function of Mn-concentration. Note that experimental data (diamonds) are plotted for effective Mn-concentration of magnetically active atoms and corresponding effective γ as found in experiment. Squares and triangles are Curie temperatures corresponding to Mn-concentrations 0.035 and 0.05, respectively, calculated for densities of holes that correspond to the experiment. The small circles (dashed line) correspond to uncompensated samples $\gamma = 1$.

exchange coupling corresponding to a measured carrier density n_h (or, alternatively via the experimentally determined parameter γ_{eff}). The main features of the above model are also supported by recent first-principles calculations [47]. Technically, one needs to determine exchange parameters, Eq. (14), but for concentration x and the effective number of carriers n_h treated as independent parameters. This is not a straightforward task in the framework of the first-principle theory without adjustable parameters, but it could be achieved with help of co-doping by impurities which have negligible influence on electronic properties of the alloy at the Fermi energy which is relevant for coupling between impurities [11]. For example, the Zn-doping on Ga-sublattice doping can increase the number of carriers. Similarly, the doping by Se-atoms on As-sublattice or by As-antisites decrease the number of carriers. It should be noted that co-doping is used here as a purely calculational device to control carrier density while keeping calculations fully selfconsistent.

The results are summarized in Fig. 5 where, for comparison, also results for $\gamma = 1$ (see also Fig. 3) are shown (small differences are due to an improved statistics). In the same figure are also given experimental data for nominal Mn-concentration of 0.067 % but for a different annealing corresponding to different effective Mn-concentrations [39]. We observe, that well-annealed samples of highest T_c are in very good agreement with the calculated values for uncompensated samples ($\gamma = 1$). We remark that $\gamma = 1$ curve can be accurately parameterized up to $x_{\rm Mn} = 0.1$ by the curve $T_c \approx A(x_{\rm Mn} - x_c)^{1/2}$, where $x_c = 0.0088$ and A = 649 K. Deviation from $\gamma = 1$ curve is small for intermediate T_c but it becomes increasingly visible for as-grown samples. For example, T_c of as-grown sample which corresponds to $\gamma_{\rm eff}=0.52$ and $x_{\rm eff}=0.035$ agrees well with the calculated value (square symbol). A similarly good agreement is obtained also for other, differently annealed samples. One can thus conclude that the present parameter-free theory is able to account for both well-annealed and as-grown (Ga,Mn)As samples. Based on a good agreement with experiment one can also conclude that the dominating mechanism for the reduction of the Curie temperature of as-grown samples as compared to well-annealed ones is the presence of Mn-interstitials.

V. CONCLUSIONS AND PROSPECTS

We have presented a unified approach to describe electronic, structural, and magnetic properties of diluted magnetic semiconductors based on the GaAs host. Our approach is based on the first-principles electronic structure calculations which take into account low concentrations of various defects present in the system as well as the finite lifetime due to such defects. The calculated total energies are then used to construct simple effective Hamiltonians, namely the Ising model and the (classical) Heisenberg model, with parameters which are obtained from parameter-free first principles calculations.

We have shown that a combination of first principles electronic structure calculations with a relatively simple methods of statistical mechanics applied to model Hamiltonians can give a coherent picture of the phase stability and possible ordering as well as of the critical temperatures in diluted magnetic III-V semiconductors prepared under different conditions. We have clearly demonstrated that inclusion of the randomness in positions of Mn-impurities is relevant for a good quantitative agreement between theory and experiment for both asgrown and well-annealed samples. Based on a good agreement with experiment one can conclude that the dominating mechanism for the reduction of the Curie temperature of as-grown samples as compared to well-annealed ones is the presence of Mn-interstitials.

One has to be aware that the samples studied in experiment need not be in thermodynamical equilibrium, but rather are in a metastable state corresponding to a local minimum of the thermodynamical potential. Phase stability studies based on equilibrium thermodynamics can nevertheless bring valuable information on certain trends in the structural evolution of DMSs and with respect to their stability, including the magnetic one.

The basic information obtained from structural studies based on the effective Ising model, e.g., a tendency to clustering, calculated short-range order parameters, etc. can be in turn employed in the preparation of better structural model for sampling of magnetic impurities in the Heisenberg model as it was demonstrated recently [50]. We wish to mention that the same electronic structure model can be used to calculate the transport properties of DMSs, both in the bulk phase and for the multilayer arrangement, which are based on the Kubo-Greenwood and Kubo-Landauer approaches as formulated in the framework of the CPA, respectively [51]. In this way, the finite-lifetime effects due to various impurities present in the sample including native defects and possible co-dopants are included consistently in the studies of structural, magnetic, and transport properties of the DMS because they are based on the same electronic structure calculated from first principles.
