Optimizing Expected Profit in a Multinomial Logit Model with Position Bias and Social Influence

A. Abeluik · G. Berbeglia · M. Cebrian · P. Van Hentenryck

Abstract Motivated by applications in retail, online advertising, and cultural markets, this paper studies how to find the optimal assortment and positioning of products subject to a capacity constraint and social influence. We prove that the optimal assortment and positioning can be found in polynomial time for a multinomial logit model capturing utilities, position bias, and social influence. Moreover, in a dynamic market, we show that the policy that applies the optimal assortment and positioning and leverages social influence outperforms in expectation any policy not using social influence.

1 Introduction

One of the most studied problems in the area of revenue management is the optimal assortment problem. Informally, the problem consists in selecting a subset of products to offer to consumers so that the expected profit is maximised. Such optimal subset depends on the profits obtained by selling a unit of each of these products, as well as the purchasing behaviour of the consumers, which is represented using a discrete choice model. Most of the discrete choice models of practical significance are special cases of the Random Utility Model (RUM) in which each product *i* is characterized by a distribution D_i that represents the consumer utility. When offered a subset *S* of products, each consumer can then be viewed as a realization of all the distributions D_i and she picks the product in *S* with the highest utility. Some of the most studied discrete choice models are the Multinomial Logit (MNL) [11], the *nested multinomial logit* (NMNL) [17] and the Mixed Multinomial Logit (MMNL) [5]. When consumers choose products according to the MNL model, the optimal assortment problem can be solved efficiently [16]. This result was later extended in [13] to the case in which there is a constraint on the maximum number of products that can be offered. However, when consumers follow either an NMNL or an MMNL model, the optimal assortment problem is NP-hard [6, 14, 2].

The underlying assumption in the vast literature that studies the optimal assortment problem is that the consumer choice behaviour is solely affected by the subset of products being offered: The particular

way in which the products are displayed has no importance. This assumption, however, is violated in many real-world situations. Moreover, in many settings, social signals (e.g., quality ratings and recommendations) are displayed together with the products. Once again, this is traditionally ignored in the literature.

The problem of finding an assortment and positioning of products that maximizes profit subject to capacity constraints and social influence has numerous practical applications, from retail to online advertising and cultural markets. Position bias is pervasive in E-Commerce and recommendation systems (e.g., [8,10,12]), while many settings also display of social signals to influence consumers. Social science studies often feature both position bias and social influence [9,15]. It is thus important for practical applications to study a model that jointly considers position bias, social influence, and limits on the number of displayed products although, to our knowledge, such a model has not been analyzed so far.

This paper addresses this gap and studies a multinomial logit model that captures these three elements. It contains two main technical contributions:

- 1. It shows that optimizing the expected profit for this multinomial logit model can be performed in polynomial time. This result holds although the traditional regularity assumption is violated in this setting.
- 2. It proves that it is beneficial to use social influence for maximizing the expected profit. In particular, the paper proves that, in a dynamic market based on the model, the policy that uses social influence and applies the optimal assortment and positioning at every step outperforms in expected profit any policy not using social influence.

The first contribution generalizes the seminal results in [13] to include position bias and to study the role of social influence. The second contribution sheds new light on social influence. Indeed, most studies focus on showing the negative side of social influence, i.e., the increased unpredictability and inequalities it creates. This paper shows its main positive aspect: Its ability to improve the efficiency of the market.

The rest of the paper is organized as follows. Sections 2 and 3 present the problem specification and related work. Section 4 proves that maximizing the expected profit in the proposed model can be performed in polynomial time. Section 5 demonstrates the benefits of social influence. Section 6 concludes the paper.

2 Problem Specification

Consider a market with N products $\mathcal{P} = 1, ..., N$, where only $c \leq N$ products in \mathcal{P} can be displayed. In the MNL model, each product $i \in \mathcal{P}$ has an utility

$$u_i = q_i + \epsilon_i$$

where q_i is a constant representing the inherent quality of product i and ϵ_i is a random variable following a Gumbel distribution with zero mean and representing the error term. The no-purchase option, denoted by 0, is added by assuming its utility is zero, i.e., $e^{q_0} = 1$. Given a subset $S \subseteq \mathcal{P}$, the probability that a consumer chooses product $i \in S$ is

$$P_i(S) = \frac{e^{q_i}}{\sum_{j \in S} e^{q_j} + 1}$$

In this paper, we consider the optimal assortment problem in which consumers follow the MNL but each product must be displayed in one of N positions, each of which has a visibility $\theta_i \ge 0$ $(1 \le i \le N)$. Without loss of generality, we assume $\theta_1 \ge \theta_2 \ge \cdots \ge \theta_N \ge 0$. A position assignment is an injective function $\sigma: S \to 1..N$ that assigns a position to each product in an assortment $S \subseteq \mathcal{P}$. The intrinsic utility u_i of product *i* when displayed in position *j* is shifted by a factor $\ln \theta_j$. Since

$$e^{q_i + \ln \theta_j} = e^{\ln \theta_j} e^{q_i} = \theta_i e^{q_i},$$

the probability of selecting product i becomes

$$P_i(S,\sigma) = \frac{\theta_{\sigma_j} u_i}{\sum_{j \in S} \theta_{\sigma_j} u_j + 1}.$$

where $u_i = e^{q_i}$ for notational simplicity. Note that, for any assortment S and position assortment σ , we have

$$\sum_{i \in S} P_i(S, \sigma) + P_0(S, \sigma) = 1,$$

where $P_0(S, \sigma)$ is the no-choice option.

Let r_i denote the marginal profit of product *i* and assume that the no-purchase option has no profit, i.e., $r_0 = 0$. The first problem considered in the paper is to find a polynomial-time algorithm that maximizes the expected profit in this market, i.e.,

$$U(S,\sigma) = \sum_{i \in S} r_i P_i(S,\sigma).$$

Definition 1 (Capacitated Multinomial Logit Assortment and Positioning Problem) With the above notations, the Capacitated Multinomial Logit Assortment and Positioning Problem (CMLAPP) is defined as

$$Z^* = \max \left\{ U(S,\sigma) \mid S \subseteq \mathcal{P} \; \land \; |S| \leq c \; \land \; \sigma : S
ightarrow 1..N
ight\}.$$

This paper also considers a dynamic market where the perceived product quality u_i varies along time according to a social influence signal. Consider $d_{i,t}$ the number of selections (e.g., the number of downloads in a music market or the number of clicks on a website) of product *i* at time *t*. We define the utility of product *i* at time *t* as a combination of the inherent quality of the product u_i and a non-decreasing and positive social influence function $f(\cdot)$, i.e.,

$$u_{i,t} = u_i + f(d_{i,t}).$$

In this dynamic market,

$$d_{i,t} = d_{i,t-1} + 1$$

if product i is selected at step t and $d_{i,t} = d_{i,t-1}$ otherwise. More formally, the probability of selecting product i for social signal d given a subset S and a position assignment σ is given by

$$P_i(S, \sigma, d) = \frac{\theta_{\sigma_j}(u_i + f(d_i))}{\sum_{j \in S} (\theta_{\sigma_j}(u_i + f(d_i))) + 1}$$

In a dynamic market with T steps, the expected profit can be defined by the following recurrence:

$$U_t(d) = \max_{S,\sigma} \sum_{i \in S} P_i(S,\sigma,d) (r_i + U_{t+1}(d[i \leftarrow d_i + 1])) \ (t \in 1..T) \\ U_{T+1}(d) = 0$$

where $d[i \leftarrow v]$ represents the vector d where element i has been replaced by v and $U_1(\langle 0, \ldots, 0 \rangle)$ denotes the overall expected profit.

When there is no social signal, the optimization problem is the same at each step t and the policy that selects an optimal solution to the CMLAPP for each t is optimal. The second problem considered in this paper is to determine that the effect of social influence on this policy.

3 Related Work

This section reviews relevant related work, including some algorithmic concepts that are important for the results of this paper.

3.1 The MusicLab Model

The problem studied in the paper is motivated by the seminal study of social influence in the MUSICLAB [15] and the descriptive model introduced in [9] to capture these experiments. In the MUSICLAB, participants enter a cultural market and are presented with a number of songs. Only the title of the song and the band name are displayed. A market participant chooses a song and, after listening to the song, is given the opportunity to download it. The MUSICLAB experiments were designed to measure the impact of social influence in cultural markets. Participants were split into a number of independent worlds. In all but one world, the participants were shown a social signal, i.e., the number of downloads of each song in their world. In the last world, no social signal was displayed. The experiments were used to demonstrate the unpredictability of cultural markets in the presence of social influence.

The descriptive model introduced in [9] was used to capture and reproduce the essence of this cultural market. The model is defined in terms of a market composed of n songs. Each song $i \in \{1, ..., n\}$ is characterized by two values:

- 1. Its appeal A_i which represents the inherent preference of listening to song *i* based only on its name and its band;
- 2. Its quality q_i which represents the conditional probability of downloading song *i* given that it was sampled.

The MUSICLAB experiments present each participant with a playlist π , i.e., a permutation of $\{1, \ldots, n\}$. Each position p in the playlist is characterized by its *visibility* v_p which is the inherent probability of sampling a song in position p. The model specifies the probability of listening to song i at time k given a playlist σ as

$$p_{i,k}(\sigma) = \frac{v_{\sigma_i}(\alpha A_i + D_{i,k})}{\sum_{j=1}^n v_{\sigma_j}(\alpha A_j + D_{j,k})},$$

where $D_{i,k}$ is the number of downloads of song *i* at time *k* and $\alpha > 0$ is a scaling factor which is the same for all songs. Observe that the probability of sampling a song depends on its position in the playlist, its appeal, and the number of downloads at time *k*.

This paper generalizes the MUSICLAB model in multiple ways: It uses a well-known multinomial logit model, introduces a limit on how many products can be displayed (which is more realistic in practice), and embeds the social influence signal in a non-decreasing, positive function f. All three generalizations are significant for practical applications.¹ This paper generalizes our own results on the MUSICLAB [1] and show that, even in this more general setting, the expected profit can be optimized in polynomial time and social influence is beneficial in maximizing expected profit.

3.2 E-Commerce Models

This paper also provides an alternative to traditional models from the E-Commerce literature. In E-Commerce, the *click-through rate* (CTR) for a link l is the probability that l receives a click. This probability

¹ The MUSICLAB was introduced for showing the unpredictability introduced by social influence in cultural markets.

may depend on a combination of factors, the most significant ones being the relevance of the content and the positioning of the links. The simplest model, which is pervasive in the e-Commerce literature (e.g., [8,12]), assumes that the CTRs are independent. More precisely, this model assumes that the CTR of link l is the product of a position effect θ_k and a relevance effect q_l . This simplification makes the model attractive both from theoretical and practical standpoint. For example, this model is widely adopted in online advertising, since the optimal allocation is simply obtained by sorting the advertisements by decreasing $\theta_k q_i$. However, the independence assumption of CTRs is not always justified. Experimental analysis using eye-tracking [7, 3] has inspired cascade models, first introduced in [4] and subsequently generalized. Informally speaking, the cascade model captures a sequential search, where users consider links from top to bottom and only look at the next link if the previous link was not selected. The model studied in this paper presents an alternative which capture many interesting markets, while remaining tractable computationally.

3.3 Optimal Capacitated Multinomial Logit Assortment

Rusmevichientong, Shen, and Shmoys, in their seminal paper [13], consider a special case of the CMLAPP where there is no visibility component, i.e., $\theta_i = 1$ ($i \in 1..c$), and no social influence. In other words, they consider the following problem.

Definition 2 (Capacitated Multinomial Logit Assortment Problem) With the above notations, the Capacitated Multinomial Logit Assortment Problem (CMLAP) amounts to determining

$$Z^* = \max \{ U(S) \mid S \subseteq \mathcal{P} \land |S| \le c \}$$

where the profit of an assortment S is defined as $U(S) = \sum_{i \in S} r_i P_i(S)$, and the probability to select product $i \in S$ is given by $P_i(S) = \frac{u_i}{\sum_{j \in S} u_j + 1}$.

One of the main results of their paper is to show that the CMLAP can be solved in polynomial time and we now review some of the key concepts and intuition underlying their results. The optimal profit can be expressed as follows:

$$Z^* = \max\{\lambda \in \mathcal{R} \mid \exists S \subseteq \mathcal{P} : |S| \le c \land U(S) \ge \lambda\}$$

= $\max\{\lambda \in \mathcal{R} \mid \exists S \subseteq \mathcal{P} : |S| \le c \land \frac{\sum_{i \in S} u_i r_i}{\sum_{j \in S} u_j + 1} \ge \lambda\}$
= $\max\{\lambda \in \mathcal{R} \mid \exists S \subseteq \mathcal{P} : |S| \le c \land \sum_{i \in S} u_i (r_i - \lambda) \ge \lambda\}$

Observe that, for a specific λ , it suffices to rank the expressions $u_i(r_i - \lambda)$ $(i \in \mathcal{P})$ to find the subset S maximizing the term $\sum_{i \in X} u_i(r_i - \lambda)$. We can then define a function $A : \mathbb{R} \to \{S \subseteq \mathcal{P} : |S| \le c\}$ as

$$A(\lambda) = \underset{S:|S| \le c}{\operatorname{arg-max}} \sum_{i \in S} u_i (r_i - \lambda)$$

where ties are broken arbitrarily. The optimal profit can be shown to be equivalent to

$$Z^* = \max\{U(A(\lambda)) \mid \lambda \in \mathcal{R}\}.$$

It is valid to drop the condition $\sum_{i \in S} u_i(r_i - \lambda) \ge \lambda$ due to dominance properties: When the condition is violated for some λ , there exists a value $\lambda' < \lambda$ such that $U(A(\lambda)) < U(A(\lambda'))$. The key observation in [13] is that there are at most $O(N^2)$ values to consider for λ and hence at most $O(N^2)$ subsets of \mathcal{P} to consider for finding the optimal assortment.

4 Capacitated Multinomial Logit Assortment and Positioning

This section shows that the CMLAPP can be solved in polynomial time building on the techniques used for the CMLAP. The key insight is that the CMLAPP only needs to consider the candidate subsets of the CMLAP.

The first step in the proof consists in showing that there is no benefit in introducing gaps in the positioning.

Definition 3 (Gap-Free Position Assignment) Given an assortment S, a position assignment σ is gap-free if $\{\sigma_i \mid i \in S\} = 1..|S|$.

Lemma 1 There is an optimal gap-free solution to any CMLAPP.

Proof Let σ be a position assignment with gaps. Assume that no product is assigned to position k and let $l = \min\{i \in S \mid \sigma_i > k\}$ be the first product assigned to a position higher than k. Since $\theta_k \ge \theta_{\sigma_l}$, moving product l from σ_l to k increases its visibility. If this move is not profitable, it must be that

$$\frac{\sum_{i\in S} \theta_{\sigma_i} u_i w_i + (\theta_k - \theta_{\sigma_l}) u_l r_l}{\sum_{j\in S} \theta_{\sigma_j} u_j + (\theta_k - \theta_{\sigma_l}) u_l + 1} \le \frac{\sum_{i\in S} \theta_{\sigma_i} u_i r_i}{\sum_{j\in S} \theta_{\sigma_j} u_j + 1}$$

Let $R = \sum_{i \in S} \theta_{\sigma_i} u_i r_i$ and $Q = \sum_{i \in S} \theta_{\sigma_i} u_i + 1$. The above inequality becomes

$$\begin{split} l\frac{R + (\theta_k - \theta_{\sigma_l}) u_l r_l}{Q + (\theta_k - \theta_{\sigma_l}) u_l} &\leq \frac{R}{Q} \\ QR + Q \left(\theta_k - \theta_{\sigma_l}\right) u_l r_l &\leq RQ + R \left(\theta_k - \theta_{\sigma_l}\right) u_l \\ r_l &\leq \frac{R}{Q}. \end{split}$$

The last inequality states that the marginal profit of product l is smaller or equal to the expected profit. We now show that we can remove product l while not degrading the profit. Indeed, $r_l \leq \frac{R}{Q}$ implies

$$\begin{aligned} & -R\theta u_l \leq -Q\theta u_l r_l & (\cdot - \theta u_l) \\ & RQ - R\theta u_l \leq RQ - Q\theta u_l r_l & (+RQ) \\ & \frac{R}{Q} \leq \frac{R - \theta u_l r_l}{Q - \theta u_l}. \end{aligned}$$

The result follows.

Lemma 1 indicates that the position assignment of an assortment S only need to consider positions 1..|S|. Hence, the position assignment is a bijection from S to 1..|S|. As in the CMLAP, we define a function $B : \mathbb{R} \to \{X \subseteq \mathcal{P} : |X| \le c\}$ as

$$B(\lambda) = \underset{S:|S| \leq c}{\operatorname{arg-max}} \max_{\sigma: S \mapsto 1.. |S|} \sum_{i \in S} \theta_{\sigma_i} u_i \left(r_i - \lambda \right)$$

which, given a value λ , specifies the assortment producing the best profit for some optimal position assignment. The optimal position assignment σ_S^{λ} for assortment S and value λ is defined as

$$\sigma_{S}^{\lambda} = \underset{\sigma:S \mapsto 1..|S|}{\operatorname{arg-max}} \sum_{i \in S} \theta_{\sigma_{i}} u_{i} \left(r_{i} - \lambda \right),$$

Ties are broken arbitrarily in these two expressions. The optimal profit of the CMLAPP can be then reformulated as

$$Z^* = \max\{U(B(\lambda), \sigma_{B(\lambda)}^{\lambda}) \mid \lambda \in \mathcal{R}\}$$

The optimal position assignment σ_S^{λ} can be computed easily thanks to a rearrangement inequality.

Lemma 2 (Rearrangement) Let x_1, x_2, \ldots, x_n and y_1, y_2, \ldots, y_n be real numbers (not necessarily positive) with $x_1 \leq x_2 \leq \cdots \leq x_n$ and $y_1 \leq y_2 \leq \cdots \leq y_n$, and let π be any permutation of $\{1, 2, \ldots, n\}$. Then the following inequality holds:

$$x_1y_{\pi_1} + x_2y_{\pi_2} + \dots + x_ny_{\pi_n} \le x_1y_1 + x_2y_2 + \dots + x_ny_n.$$

Proof We prove the inequality by induction on n. The statement is obvious for n = 1. Suppose that it is true for n = k - 1 and consider n = k. Let m be an integer such that $\pi(m) = k$. Since $x_k \ge x_m$ and $y_{\pi(m)} = y_k \ge y_{\pi(k)}$, we have

$$(x_k - x_m) \left(y_k - y_{\pi(k)} \right) \ge 0$$

This implies that

 $x_k y_{\pi(k)} + x_m y_k \le x_k y_k + x_m y_{\pi(k)} \le x_k y_k + x_m y_k$

and hence

$$x_k y_{\pi(k)} \le x_k y_k.$$

By induction hypothesis,

$$x_1y_{\pi(1)} + \dots + x_my_{\pi(m)} + \dots + x_{n-1}y_{\pi(n-1)} \le x_1y_1 + \dots + x_my_m + \dots + x_{k-1}y_{k-1}$$

Combining these two inequalities proves the result.

The optimal position assignment must thus satisfy

$$u_{\pi_1}(r_{\pi_1}-\lambda) \geq \ldots \geq u_{\pi_{|S|}}(r_{\pi_{|S|}}-\lambda)$$

for some ranking assignment $\pi : 1..|S| \rightarrow S$ and the optimal position assignment can be defined as the inverse of π . We now show that the CMLAPP only needs to consider the assortments considered by the CMLAP.

Lemma 3 Let $\mathcal{B} = \{B(\lambda) : \lambda \in \mathbb{R}\}$ and $\mathcal{A} = \{A(\lambda) : \lambda \in \mathbb{R}\}$. Then, $\mathcal{B} \subseteq \mathcal{A}$.

Proof Consider $\lambda \in \mathcal{R}, S \in B(\lambda)$, and π be the inverse of σ_S^{λ} . π satisfies

$$u_{\pi_1}\left(r_{\pi_1}-\lambda\right)\geq\cdots\geq u_{\pi_{|S|}}\left(r_{\pi_{|S|}}-\lambda\right).$$

Consider first the case where |S| < c. Then, by optimality of $B(\lambda)$ and $\theta_k \ge 0$, it must be the case that $u_i(r_i - \lambda) \le 0$ for all $i \in \mathcal{P} \setminus S$. When |S| = c, it must be the case that

$$u_i(r_i - \lambda) \ge u_j(r_j - \lambda)$$
 $(i \in S \text{ and } j \in \mathcal{P} \setminus S)$

since otherwise swapping i and j would increase the profit. As a result, for any $S' \subseteq \mathcal{P}$ such that $|S'| \leq c$, we have that

$$\sum_{i \in S} u_i \left(r_i - \lambda \right) \ge \sum_{j \in S'} u_j \left(r_j - \lambda \right).$$

Hence $S \in \mathcal{A}$.

We are now in position to state that the CMLAPP can be solved in polynomial time.

Theorem 1 CMLAPP can be solved in polynomial time.

Proof The result follows from Lemmas 1–3 and the fact that \mathcal{A} can be computed in $O(N^2)$ time [13].

This result is particularly interesting given the fact that the CMLAPP violates the regularity assumption which states that the addition of an option to a choice set should never increase the probability of selecting an option in the original set.

Definition 4 (Regularity Assumption) Let $X \subset Y \subseteq \mathcal{P}$. The regularity assumption for the CMLAP problem states that

$$P_i(X) \ge P_i(Y) \quad \forall i \in X \cup \{0\}.$$

Lemma 4 The CMLAPP problem violates the regularity assumption.

Proof Consider two products with $u_1 = 3, r_1 = 1, u_2 = 1, r_2 = \frac{5}{4}$ and visibilities $\theta_1 = 2, \theta_2 = 1$. The optimal assortment for each value of c is given by

С	1	2
S^*	{1}	$\{2,1\}$
Z^*	0.8571	0.9167
p_0	0.1429	0.1667

where the optimal position assignment is specified by the order of the products in assortment S^* . Although the revenue Z^* increases when moving from $\{1\}$ to $\{1,2\}$, the no-purchase option satisfies

$$P_0(\{1\}, \sigma_1) < P_1(\{1, 2\}, \sigma_2)$$

for $\sigma_1(1) = 1$, $\sigma_2(1) = 2$, and $\sigma_2(2) = 1$.

5 The Benefits of Social Influence

This section proves that, under social influence, the expected profit increases over time when using the optimal assortment and position assignment. This holds regardless of the number of products, their utilities, and the visibilities. The derivation uses ranking assignments, i.e., the inverse of position assignments, since they make the notations and proofs simpler. Recall that $u_{i,t}$, the utility of product i at time t, is defined as the combination of the inherent quality of the product u_i and a non-decreasing and positive social influence function $f(\cdot)$, i.e., $u_{i,t} = u_i + f(d_{i,t})$.

In state t, the probability that product i is selected given assortment S and ranking π is

$$P_{i,t}(S,\pi) = \frac{\theta_{\pi_i} u_{i,t}}{\sum_{j \in S} \theta_{\pi_j} u_{j,t} + 1}$$

Under social influence, the expected profit over time can be considered as a Markov chain where state t + 1only depends on state t. If product k is selected at time t and if assortment S' and ranking π' are used at time t + 1 and $i \in S'$, the probability that product i is selected at time t + 1 is given by

$$\frac{\theta_{\pi'_i} u_{i,t+1}}{\sum_{j \in S': j \neq k} \theta_{\pi'_j} u_{j,t} + \theta_{\pi'_k} u_{k,t+1} + 1}$$

Since f is non-decreasing, we define $\epsilon_{i,t} = f(d_{i,t}+1) - f(d_{i,t}) \ge 0$ such that

$$u_{i,t+1} = u_{i,t} + \epsilon_{i,t}.$$

We denote by $U_{t+1}((S', \pi')|(S, \pi))$ the expected profit at time t + 1 conditional to time t if assortment S and ranking π are used at time t and assortment S' and ranking π' are used at time t + 1. The core of the proof consists in showing that

$$U_{t+1}((S^*, \pi^*)|(S^*, \pi^*)) \ge U_t(S^*, \pi^*),$$

where (S^*, π^*) is the optimal (assortment, ranking) pair at time t. The expected profit at time t + 1 conditional to time t in this context is given by

$$\sum_{j \in S^*} \left(P_{j,t}(S^*, \pi^*) \cdot \frac{\sum_{i \in S^*: i \neq j} \theta_{\pi_i^*} u_{i,t} r_i + \theta_{\pi_j^*}(u_{j,t} + \epsilon_{j,t}) r_j}{\sum_{i \in S^*: i \neq j} \theta_{\pi_i^*} u_{i,t} + \theta_{\pi_j^*}(u_{j,t} + \epsilon_{j,t}) + 1} \right) + \left(1 - \sum_{i \in S^*} P_{i,t}(S^*, \pi^*) \right) \cdot U_t(S^*. \pi^*).$$

The bottom term captures the case where no product is selected at time t. while the top term captures the cases where product j is selected, which increases its perceived utility for the next time step.

Lemma 5 Let (S^*, π^*) be the optimal allocation in time step t. We have

$$U_{t+1}((S^*, \pi^*)|(S^*, \pi^*)) \ge U_t(S^*, \pi^*).$$

Proof Let $u = u_1, \dots, u_n$ represent the current state at time t. Without loss of generality, we can rename the songs so that $\pi_i^* = i$ and drop the ranking subscript π^* . We also omit writing the inclusion in S^* in the summations and use ϵ_j to denote $\epsilon_{j,t}$. The optimal expected profit at time t can be written as

$$U_t(S^*, \pi^*) = \frac{\sum_i \theta_i u_i r_i}{\sum_i \theta_i u_i + 1} = \lambda^*.$$

The expected profit $U_{t+1}((\pi^*, S^*)|(\pi^*, S^*))$ in time t+1 conditional to time t, which we denote by U_{t+1}^* , is given by

$$U_{t+1}^* = \sum_j \left(\frac{\theta_j u_j}{\sum \theta_i u_i + 1} \cdot \frac{\sum_{i \neq j} \theta_i u_i q_i + \theta_j (u_j + \epsilon_j) r_j}{\sum_{i \neq j} \theta_i u_i + \theta_j (u_j + \epsilon_j) + 1} \right) + \left(1 - \frac{\sum_i \theta_i u_i}{\sum_i \theta_i u_i + 1} \right) \cdot \frac{\sum_i \theta_i u_i r_i}{\sum_i \theta_i u_i + 1} = \sum_j \left(\frac{\theta_j u_j}{\sum \theta_i u_i + 1} \cdot \frac{\sum_i \theta_i u_i r_i + \epsilon_j \theta_j r_j}{\sum_i \theta_i u_i + \epsilon_j \theta_j + 1} \right) + \left(1 - \frac{\sum_j \theta_j u_j}{\sum_i \theta_i u_i + 1} \right) \cdot \lambda^*.$$

Proving

$$U_{t+1}^* \ge U_t(S^*, \pi^*) \tag{5.1}$$

amounts to showing that

$$\sum_{j} \left(\frac{\theta_{j} u_{j}}{\sum \theta_{i} u_{i} + 1} \cdot \frac{\sum_{i} \theta_{i} u_{i} r_{i} + \epsilon_{j} \theta_{j} r_{j}}{\sum_{i} \theta_{i} u_{i} + \epsilon_{j} \theta_{j} + 1} \right) + \left(1 - \frac{\sum_{j} \theta_{j} u_{j}}{\sum_{i} \theta_{i} u_{i} + 1} \right) \cdot \lambda^{*} \ge \lambda^{*}.$$

which reduces to proving

$$\frac{1}{\sum_{i} \theta_{i} u_{i} + 1} \sum_{j} \left[\frac{\theta_{j}^{2} u_{j} \epsilon_{j}}{\sum_{i} \theta_{i} u_{i} + \epsilon_{j} \theta_{j} + 1} \left(r_{j} - \lambda^{*} \right) \right] \ge 0$$

or, equivalently,

$$\sum_{j} \left[\frac{\theta_j^2 u_j \epsilon_j}{\sum_i \theta_i u_i + \epsilon_j \theta_j + 1} \left(r_j - \lambda^* \right) \right] \ge 0.$$

By definition of *B*, the optimality of S^* implies that $S^* \in B(\lambda^*)$. Hence, by optimality of S^* , $(r_i - \lambda^*) \ge 0$ for all $i \in S$. The result follows since, for all i, $\frac{\theta_j^2 u_j \epsilon_j}{\sum_i \theta_i u_i + \epsilon_j \theta_j + 1} \ge 0$.

We are now in position to state the main result of this section.

Theorem 2 Under social influence, the expected profit is nondecreasing over time when the optimal assortment and ranking are used at every step.

Proof Let (S^*, π^*) and (S^{**}, π^{**}) be the optimal solution in time step t and t+1 respectively. Then,

$$U_{t+1}((\pi^{**}, S^{**})|(\pi^{*}, S^{*})) \ge U_{t+1}((\pi^{*}, S^{*})|(\pi^{*}, S^{*})) \ge U_{t}((\pi^{*}, S^{*})),$$

where the first inequality follows from the optimality of (S^{**}, π^{**}) and the second inequality follows from Lemma 5.

Denote by P^* the policy that applies the optimal CMLAPP solution at each step. Theorem 2 entails an interesting corollary about P^* . Indeed, when there is no social influence, P^* outperforms any policy P since the optimization problem is the same for every step. Since P^* under social influence outperforms (in expectation) P^* with no social influence, it follows that P^* under social influence outperforms any policy not using social influence.

Corollary 1 In expectation, applying the optimal CMLAPP solution at each step with or without social influence outperforms any policy not using social influence.

6 Conclusion

Motivated by practical applications in E-Commerce and recommendation systems, this paper studied a multinomial logit model that captures position bias, social influence, and limits on how many products can be displayed. It showed how to optimize the expected profit for this multinomial logit model in polynomial time. In addition, it showed that it is beneficial to use social influence for maximizing the expected profit. Experimental results on the MUSICLAB [1], a special case of the model with no capacity constraint, an identity function f, an obligation to make a choice, indicate that the algorithm provides significant improvements in expected profit compared to simple ranking policies and that the benefits of social influence can be substantial. Future work will focus on generalizing the results to the case where market participants have different preferences.
