CDVAE: Co-embedding Deep Variational Auto Encoder for Conditional Variational Generation

Jiajun Lu, Aditya Deshpande, David Forsyth University of Illinois at Urbana Champaign {jlu23, ardeshp2, daf}@illinois.edu

Abstract

Problems such as predicting a new shading field (Y) for an image (X) are ambiguous: many very distinct solutions are good. Representing this ambiguity requires building a conditional model P(Y|X) of the prediction, conditioned on the image. Such a model is difficult to train, because we do not usually have training data containing many different shadings for the same image. As a result, we need different training examples to share data to produce good models. This presents a danger we call "code space collapse" — the training procedure produces a model that has a very good loss score, but which represents the conditional distribution poorly. We demonstrate an improved method for building conditional models by exploiting a metric constraint on training data that prevents code space collapse. We demonstrate our model on two example tasks using real data: image saturation adjustment, image relighting. We describe quantitative metrics to evaluate ambiguous generation results. Our results quantitatively and qualitatively outperform different strong baselines.

1. Introduction

Many vision problems have ambiguous solutions. There are many motion fields consistent with an image [19, 25, 26]. Similarly, there are many shading fields consistent with the layout of an image (Figure 1); many good ways to colorize an image [3, 27, 29]; many possible ways to adjust the saturation of an image (Figure 1); many possible long term futures for an image frame [30]; and so on. For each of these problems, one must output a spatial field Y for an input image X; but Y is not uniquely determined by X. Worse, Y has complex spatial structure (for example, saturation at a pixel is typically similar to the saturation at the next pixel, except over boundaries). It is natural to build a generative model of Y, conditioned on X, and draw samples from that model. Towards this end, recent work has modified a strong generative model for images that uses latent variables, the

Figure 1. We describe a method to learn a multimodal conditional distribution P(Y|X) between output spatial field Y and an input image X. We learn the model from "scattered" data, where in training one never sees two distinct Y values for one particular X value. Our method allows us to sample and produce new saturation and shading fields for input images.

variational auto-encoder (VAE) of [7], to produce a conditional VAE (CVAE) [19, 25, 26]. The very high dimension and complex spatial covariances of *Y* are managed by the underlying latent variable model in the CVAE.

However, building a good conditional model still poses some challenges. In most practical vision problems, the training dataset we can access is "scattered", and the model is multimodal. Scattered training data consists of pairs of (y_i, x_i) , but we never see multiple different values of y_i for one particular x_i . Practical vision models compute some intermediate representation c(x) (which we call the "code"), and predict y from that intermediate representation and a random (or latent) variable y. Write y = F(y; c(x)). The hope is that different choices of the random variable will produce different values of y, and we can therefore predict the entire gamut of outputs (shading, motion field, saturation etc.). This implies that the method can represent a multimodal P(Y|X).

Figure 2. The horizontal axis is the input x, vertical axis is the output y and labels A, B and C are the codes c(x). With a good choice of code (left), F is forced to use random variable u to produce different y for similar x. With a bad choice of code (right), F can choose to ignore u since it has access to different codes for similar x. This results in incorrect smoothing and generalization.

This setting presents a difficulty. To build a plausible conditional model, we must smooth. The model smooths by allowing examples with similar codes to "share" y values. In turn, the choice of code is crucial, and a poor choice of code can result in a method that appears to work well, but does not. Figure 2 illustrates this point. The figure shows two possible choices of code for a particular dataset. In the good choice of code, F is forced to use the random variable to produce distinct values of y for similar x, because similar x result in similar codes. In the poor choice of code, similar x can have different codes (viz. different codes A and B for similar x in the right side of Figure 2) and vice versa. Then, F can largely ignore the random variable, but simulates a multimodal process by producing very different y for quite similar x using the different c(x). This means the network we have trained will (a) not be effective at making diverse predictions and (b) may change its prediction very significantly for a small change in x, in a manner that is uncontrolled by the code. This is not desirable behavior.

We call the effect "code collapse", because the network is encouraged to produce similar codes for different inputs. The result is a model with imperfect diversity and generalization, but good loss on scattered training data. The absence of variance, in what should be a diverse pool of output predictions, is a strong diagnostic indicator of code collapse. We exploit this indicator and show that our baselines, particularly the CVAE, generate low variance and therefore suffer from code collapse (Section 5.2, Figure 5).

The key problem, resulting in code collapse, is that the current training procedures have no term to force a good choice of codes. For example, VAE loss requires the code distribution to look like a standard normal distribution. This loss does not force it to preserve the similarity, dissimilar input images can be closer and similar inputs further apart in the code space. Recent work shows that better generative models are obtained by conditioning on text-

embeddings [15] or pre-trained features from visual recognition network [12]. This suggests that using an embedding with some structure is better than conditioning on raw pixels (with high-capacity networks).

In our approach, instead of using a fixed embedding as input, we use raw pixels but guide the codes (or intermediate representation) with a metric constraint. Our metric term encourages codes c(x) for distinct x to be different and codes for similar x to be similar. This prevents code collapse. To ensure that F(u;c(x)) will vary for similar c(x), we use a Mixture Density Network (MDN) [2]. MDN explicitly models a multimodal conditional distribution. We call our model CDVAE (Co-Embedding Deep Variational Auto Encoder).

We apply CDVAE to two novel (from the point of view of automated editing) problems: (a) Photo Relighting, (b) Image Resaturation (Section 4). In relighting (or reshading), we decompose the image into shading and albedo, then produce a new shading field consistent with the albedo field. In resaturation, we produce a new saturation field and apply it to the image. In each case, the resulting image should look "natural" – like a real image, but differently illuminated (reshading) or with differently color saturated objects (resaturation). In all cases, our model outperforms strong baselines (including the CVAE).

Contributions:

- We describe a novel method to build conditional models for extremely demanding datasets (Section 3, Figure 3) and apply it to photo-editing tasks (Section 4).
- We show how to regularize our model so that the latent representation is not distorted, and this helps us improve results (Section 3.2 and Figure 5).
- Our method is compared to a variety of strong baselines, and produces predictions that (a) have high variance and (b) have high accuracy (Section 5.3 and Section 5.2). Our method clearly outperforms existing models.
- Training previous conditional models is hard, these models tend to either go to code collapse or random prediction. Our methods can avoid code collapse and create multiple distinct plausible results (Section 5.4 and Figure 6).

2. Related Work

Generating a spatial field with complex spatial structure from an image is an established problem. Important application examples, where the prediction is naturally ambiguous, include colorization [4, 9, 29], style transfer [5], temporal transformations prediction [30], predicting motion fields [19, 25, 26], and predicting future frames [24].

Figure 3. Left Our training architecture for CDVAE; and Right Test-time architecture of CDVAE. We use two deep variational autoencoders (DVAE), one for the conditioning image x_c and another for generated image x_g . Each DVAE has two layers of latent gaussian variables and we use the ladder VAE architecture of [20]. Embedding guidance introduces metric constraints on the code space z_c to prevent code collapse. And, MDN models the multimodal distribution between z_g and z_c . During test, we sample multiple z_g from MDN for a given input. We decode these different z_g to obtain multiple predictions.

This is usually treated as a regression problem; current state of the art methods use deep networks to learn features. However, predicting the expected value of a conditional distribution, through regression, works poorly, because the expected value of a multimodal distribution may have low probability. While one might temper the distribution (eg [29]), the ideal is to obtain multiple different solutions.

One strategy is to draw samples from a generative model. Generative models of images present problems of dimension; these can be addressed with latent variable models, leading to the variational autoencoder (VAE) of [7]. As the topic attracts jargon, we review the standard VAE briefly here. This approach learns an encoder E that maps data xinto a continuous latent variable z = E(x) (the codes), and a decoder D that maps z to an image $\hat{x} = D(z)$. Learning ensures that (a) x and D(E(x)) are close; (b) if ξ is close to z, then $D(\xi)$ is close to D(z); and (c) z is distributed like a standard normal random variable. Images can then be generated by sampling a standard normal distribution to get ξ , and forming $D(\xi)$. This is a latent variable model, modelling P(x) as $P(x) = \int_z P(x|z)P(z)dz$. P(x|z) is represented by the decoder, we use an auxiliary distribution Q = P(z|x) for P(z), where P(z|x) is now the encoder. Learning is by maximizing a lower-bound on log-likelihood (Equation 1)

$$VAE(\theta) = \sum_{data} \mathbb{E}_{Q}[\log P(x|z)] - \mathbb{D}(Q||P(z)) \quad (1)$$

where θ are the parameters of encoder and decoder networks of the VAE.

Current generative models are reliable in simple do-

mains (handwritten digits [7, 18]; faces [7, 8, 16]; and CI-FAR images [6]) but less so for general images. Improvements are available using multiple layers of latent variables (a DVAE) [16]. Models can be trained with adversarial loss [14]. However, these deep models are still hard to train. The ladder VAE imposes both top-down and bottom up variational distributions for more efficient training [20].

The generative model needs to be conditioned on an image, and needs to be multimodal. Tang et al. give a multimodal conditional model [21], but the conditioning variables are binary. A conditional variational autoencoder (CVAE) [19] conditions the decoder model on a continuous representation produced by a network applied to x. This approach has been demonstrated on motion prediction problems [25, 30].

We use the mixture density network (MDN) in our models to capture the underlying multimodal distribution [2]. MDN predicts the parameters of a mixture of gaussians from real-valued input features. MDNs have been successfully applied to articulatory-acoustic inversion mapping [17, 22] and speech synthesis [28].

3. Method

Our CDVAE consists of two deep variational auto encoders (DVAE) [16] and a mixture density network (MDN) [2]. An overview of the CDVAE model is shown in Figure 3.

Our architecture is, we use two DVAEs to embed the conditioning image x_c (or X from Section 1) and the generated image x_g (or Y from Section 1) into two low-dimensional latent variables (or code spaces) z_c and z_g . The

generated image corresponds to output spatial field viz. saturation or shading etc. and the conditioning image is the input image viz. intensity or albedo etc. Next, we regularize the latent variables z_c with embedding guidance (or metric constraints) such that the similarity in input space is maintained (Section 3.2). Since our problem is ambiguous, the conditional distribution between z_g and z_c is multimodal. MDN allows us to fit a multimodal gaussian mixture model (GMM) between the conditioning code z_c and the generated code z_g (Section 3.1). At test time, we sample from this multimodal GMM ($z_g \sim MDN$) and use the decoder of the generated image DVAE ($Decoder(z_g)$) to predict different shading, saturation for a single input image.

In Figure 3, we simplify and show a single layer of latent variables. In practice, our DVAE utilizes multiple layers of gaussian latent variables. This hierarchical variational auto encoder architecture captures complex structure in the data, and provides good practical performance.

We jointly train the two DVAEs and the MDN, allowing them to adapt and mutually benefit each other. Joint training also enables CDVAE to model a joint probability distribution of x_c and x_g , instead of a conditional probability distribution (viz. like a CVAE). The joint probability model allows for more smoothing between data points. In CDVAE, we optimize the joint probability model $P(x_c, x_g)$ during training (Refer Equation 25). At test time, we remove the decoder for the conditioning layer and the encoder for the generated layer. This converts the joint model of CDVAE into a conditional model $P(x_g|x_c)$. We can then sample this conditional model to generate diverse outputs. Similar to VAE probability model, we write the joint probability by marginalizing over the joint distribution $P(z_g, z_c)$

$$P(x_c, x_g) = \int_{z_c} \int_{z_g} P(x_c|z_c) P(x_g|z_g) P(z_g, z_c) dz_g dz_c$$
(2)

In Section 3.1, we derive the loss terms corresponding to this joint probability model of CDVAE.

3.1. CDVAE Loss

In CDVAE, we use two multi-layer variational auto encoders (DVAE), one for x_c and one for x_g . Additionally, we have an MDN that models the relationship between the embeddings z_c and z_g . The loss function \mathcal{L}_{CDVAE} corresponding to the CDVAE joint model $P(x_c, x_g)$ is a combination of the two DVAE models and the conditional probability model of MDN. In Equations 1 and 25, assume it is possible to encode x_c without seeing x_g , then we can use the auxiliary sampling distribution $Q = P(z_c|x_c)P(z_g|x_g)$ for our CDVAE. If $P(z_g, z_c) = P(z_g)P(z_c)$ in Equation 25, we can separate out the product terms of joint probability model. Taking negative log-likelihood, we obtain separate additive loss terms for each DVAE. Write DVAE(θ) for the

Figure 4. We use Niyogi [13] to build an embedding which preserves metric relations between data points. Our input feature vector to [13] is constructed in three parts. First part is the semantic label distribution, which describes the object label percentages in the image (viz. 0.5 cat and 0.5 dog etc.). Second part is the object layout, which includes information of spatial layout percentages. The last part is resized image pixels, which provides low level image information.

loss function of a DVAE with weights (or parameters) θ , which has the standard form of a VAE loss (Equation 1). Write the loss of the DVAE for the generated image x_g as DVAE(θ_g) (similarly for x_c). Write loss for the MDN as \mathcal{L}_{mdn} . We can then derive the loss function for CDVAE (Equation 3),

$$\mathcal{L}_{CDVAE} = \text{DVAE}(\theta_c) + \text{DVAE}(\theta_q) + \mathcal{L}_{mdn}(\theta_c, \theta_q)$$
 (3)

Our MDN estimates the conditional probability model $P(z_g|z_c)$. For each input code z_c , our MDN estimates the parameters of a K component gaussian mixture distribution with mixture coefficients π_i , means μ_i and fixed diagonal covariance σ_i^2 . The loss \mathcal{L}_{mdn} is obtained by taking the negative log-likelihood of this conditional distribution,

$$\mathcal{L}_{mdn} = -E_Q \left[\log \sum_{k=1}^K \pi_k(z_c) \mathcal{N}(z_g | \mu_k(z_c), \sigma_k^2(z_c)) \right]$$
(4)

We use an inference method [20] that co-relates the latent variables of the encoder and the decoder. This speeds up the training. Refer to the supplementary materials for the detailed derivations.

3.2. Embedding Guidance: Preventing code collapse

Vanilla DVAEs have difficulty in learning a code space which encodes the complex spatial structure of the output. The code space learned by a DVAE appears to be underdetermined, especially for large and complex datasets. This is a common failure mode of VAEs. For our conditional models, it is desirable that codes for "similar" inputs are nearby, and codes for "very different" inputs are further apart. This discourages the method from grouping together very different inputs. It also prevents similar images from having

different codes, and therefore avoids incorrect smoothing of the model (See Figure 2). We guide the codes (at multiple layers) to be similar to a pre-computed embedding. Our pre-computed embedding is such that it preserves the similarity observed in input domain. Refer to Figure 4 and supplementary material for the details of our pre-computed embedding. Write p for the pre-computed embedding and z_c for the gaussian latent variables of the network. We use the L_2 -norm between p and z_c as a loss term

$$\mathcal{L}_{embed} = \|z_c - p\|_2^2 \tag{5}$$

Write \mathcal{L} for the final loss function with the additional regularization in the form of embedding guidance

$$\mathcal{L} = \mathcal{L}_{CDVAE} + \lambda \mathcal{L}_{embed} \tag{6}$$

We use a large value of λ when training starts and gradually reduce it during the training process.

3.3. Post Processing

Current deep generative models only handle small images, for our case 32×32 , and they generate results without high spatial frequencies. We post process generated images for viewing at high resolution (not used in any quantitative evaluation). Our post processing upsamples results to a resolution of 512×512 , with more details. We aggressively upsample the generated fields with the approach in [10], which preserves edges during upsampling. In particular, the method represents a high resolution field by a weight and an orientation value at each sample point; these parameters control a basis function placed at each sample, and the field at any test point is a sum of the values of the basis functions at that point. The sum of basis functions includes only those basis functions in the same image segment. Write Interp($\mathbf{w}, \theta; \mathcal{S}(I)$) for the high resolution field produced by interpolating a weight vector w and a vector of orientations θ , assuming a segment mask S(I) obtained from the high resolution grey level image. Write $Y^{(d)}$ for a low resolution field produced by the decoder, and $\downarrow G_{\sigma}*$ for a process that smooths and downsamples. We solve

$$\downarrow G_{\sigma} * (Interp(\mathbf{w}, \theta; \mathcal{S}(I))) = Y^{(d)}$$

for \mathbf{w} , θ , regularizing with the magnitude of \mathbf{w} . This produces a high resolution field that (a) is compatible with the high resolution edges of the grey level image (unlike the learned upsampling in common use) and (b) produces the decoder sample when smoothed.

For relighting and saturation adjustment tasks, we polish images for display by using detail maps to recover fine scale details. The detail map is calculated by taking the conditioning image I_c and subtracting the output produced by the conditioning image decoder with the code z_c . This

captures the high frequency details lost during the neural network process. We get our result $\hat{I_q}$ as

$$\hat{I}_q = \text{CDVAE}(z_q) + (I_c - \text{CDVAE}(z_c)) \tag{7}$$

4. Applications

We apply our methods to two different ambiguous tasks, each of which admits both quantitative and qualitative evaluations.

Photo Relighting (or Reshading): In this application, we predict new shading fields for images which are consistent with a relit version of the scene. We decompose the image into albedo (the conditioning image x_c), and shading (the generated image x_g). In real images, shading is quite strongly conditioned by albedo because the albedo image contains semantic information such as the scene categories, object layout and potential light sources. A scene can be lighted in multiple ways, so relighting is a multimodal problem. We use the MS-COCO dataset for relighting (Section 5.1).

Image Resaturation: Here, we predict new saturation fields for color images, i.e. we modify color saturation for some or all objects in the image. We transform the input RGB color image into HSV color space, and use the value channel as our conditioning image and the saturation channel as our generated image. We use CDVAE to generate new saturation fields consistent with the input value image. Combining the new saturation fields with H and V channels leads to new versions of an image, with edited saturation. See the grilled cheese on the broccoli in Figure 1 which demonstrates that we obtain natural edits. Again, we use the MS-COCO dataset for this application (Section 5.1).

5. Results

To evaluate the effectiveness of our method, we compare with recent strong methods (Section 5.3). We also evaluate different variants of our method. We perform quantitative and qualitative comparison on applications of photo relighting, image resaturation. Quantitative results (Section 5.2, Figure 5) are computed on the network output, without any post processing. Images shown for qualitative evaluation of resaturation and reshading (Section 5.4, Figures 1, 6, 8 and 7) are post processed using the steps described in Section 3.3. We downsample all the input images to 32×32 dimensions, and all neural network operations before post processing are performed on this image size. After our CD-VAE model generates samples, our post processing upsamples it to a resolution of 512×512 .

5.1. Datasets

MS-COCO: We use MS-COCO dataset for our both the tasks, photo relighting and image resaturation. It is a

Figure 5. Comparison to baselines (Section 5.3) on two tasks: a) photo relighting, b) image resaturation. Vertical axis is error of closest sample to the ground truth, and horizontal axis is variance of predicted samples (bottom right is better). Both are calculated by sampling 100 outputs from all conditional models. In all tasks, CVAE has low variance for generated results, suggesting the method is poor at producing diverse samples. The nearest neighbor has higher variance but cannot predict samples close to ground-truth (higher minimum error). For our CDVAE, the performance increases with 12 MDN gaussian kernals as opposed to 4 and embedding guidance is useful (CDVAE noemb's performance drops). Tables with detailed numbers are in the supplementary materials. CGANs and Conditional PixelCNN (CPixel) have higher minimum error, indicating they produce less natural output spatial fields.

Figure 6. Qualitative comparisons for Photo Relighting (top) and Image Resaturation (bottom). The first column is the input image. Nearest neighbor creates inconsistent visual artifacts, since it is a non-parametric method with little awareness of the content and spatial structure. CVAE generates low diversity. Notice the diversity in outputs of PixelCNN and CGANs is also limited. In contrast, our CDVAE generates two plausible different relighted scenes and it generates two reasonable resaturation outputs (high and low saturation) different from original input. Note that, without the embedding constraint (CDVAE noembed), we observe code collapse and same predictions.

wild dataset (unlike the structured face data commonly used by generative models), and has complex spatial structure. Typically, such data is challenging for VAE-based methods. We use train2014 (80K images) for model training, and sample 6400 images from val2014 (40K images) for testing. For photo relighting, intrinsic image decomposition method from [1] is used to obtain albedo and shading images. For image resaturation, we transform the image from RGB space to HSV space.

5.2. Quantitative Metrics and Evaluation

Error-of-Best to ground truth: We follow the motion prediction work [25] to use error-of-best to ground truth as an evaluation metric. We draw 100 samples for each conditional model and calculate the minimum per pixel error to ground truth fields. A better model will produce smaller values, because it should produce some samples closer to the ground truth.

Variance: A key goal of our paper is to generate diverse solutions. However, no current evaluation regime can tell whether a pool of diverse solutions is right. We opt for the strictly weaker proxy of measuring variance in the pool, on the reasonable assumption that diverse predictions for our problems must have high variance. Thus, procedures that produce low variance predictions are clearly unacceptable. Clearly, it is not enough just to produce variance – we want the pool to contain appealing diverse predictions. To assess this, we rely on qualitative evaluations (Figures 6, 7, 8). The supplementary materials contain many additional qualitative results.

To compute variance, we obtain the values for $16 \ (4 \times 4)$ equally spaced grid (since distant pixels are de-correlated to some extent) of pixels in our 32×32 prediction. We collect these values across 100 samples, and compute the variance at each grid point across samples. We report this average variance vs. minimum error (See Figure 5). In particular, a method with more diverse output predictions should result in higher variances and one of them should also be close to the ground-truth (therefore, low minimum error). Specifically, we need to be in the bottom-right part of Figure 5, which our CDVAE achieves.

Therefore, our CDVAE model creates results with desirable properties: lower error-of-best to ground truth and large variance. Our CDVAE model produces better results with more gaussian kernels (CDVAE12 vs. CDVAE4) and performance drops (higher minimum error and low variance) when no embedding guidance is used (CDVAE4 noemb).

5.3. Baseline Methods

Nearest neighbor (NN): We perform top—k nearest neighbor (NN) search in x_c space, and return the k corresponding x_q as multiple outputs. Gaussian smoothing is ap-

plied to returned x_g to remove inconsistent high frequency signal. Since our training data does not have explicit one-to-many correspondences, NN is a natural strong baseline. It is a non-parametric method to model multimodal distribution by borrowing output spatial fields (we also smooth these) from nearby input images.

Conditional variational autoencoder: We implement a CVAE similar to [25]. We cannot use [25] since their architecture is specific to prediction of coarse motion trajectories. Our decoder is modelled on the DCGAN architecture of Radford et al. [14] with 5 deconvolution layers, and we use codes of dimension 64 (to be consistent with CDVAE). Our image tower and encoder tower use 5 convolutional layers (mirror image of the decoder). We use the same strategy as [25], i.e. we spatially replicate code from encoder and multiply it to the output of image tower. The decoder takes as input the result of this. We train our CVAE with the standard pixel-wise L2 loss on output and KL-divergence loss on the code space. At test time, codes are randomly sampled from the normal distribution.

Conditional GAN: CGAN [11] is another conditional image generation model. It uses a regularized code (drawn from a uniform distribution) along with a fixed embedding of the conditioning image as input. We observe that CGAN achieves higher minimum error (or error-of-best) and lower variance as compared to CDVAE (See Figure 5). Therefore, we generate better (lower minimum error) and more diverse (higher variance) predictions that CGAN. These metrics are explained in detail in Section 5.2.

Conditional PixelCNN (CPixel): Conditional Pixel-CNN [23] uses masked and gated convolutions (sigmoid and tanh activations layers multiplied). The receptive field of masked convolutions mimics the causal dependency and gated convolutions approximate the behavior of LSTM gates in recurrent architectures. Therefore, Pixel-CNN (CPixel) feasibly approximates the compute intensive recurrent architectures [6] for image generation. However, their receptive field grows linearly and handling long-scale effects is difficult. Our results are qualitatively better than PixelCNN, we believe our DVAE with fully-connected layers is better at capturing the global structure given the coarse resolution used. Note, our CDVAE has lower minimum error than PixelCNN (Figure 5).

5.4. Qualitative Evaluation

In addition to outperforming baselines on quantitative results, our method generates better qualitative results. Samples from our jointly trained conditional model smooth information across "similar" images, allowing us to produce aligned, semantically sensible and reasonable diverse predictions. Our qualitative comparisons with other methods for the two tasks is shown in Figure 6. In both examples, we generate plausible and diverse relighted scenes and re-

Figure 7. For each input image in the first column, we sample four different saturation fields from our CDVAE model. Our CDVAE model automatically generates multiple natural saturation adjustments. We learn our conditional distribution from MS-COCO dataset and the outputs show that our prediction respects spatial structure (saturation effects do not bleed across edges) and semantics (objects do not get unnatural or synthetic colors). (Figure best viewed in high resolution)

saturated image.

Image Resaturation: More results for image resaturation with our CDVAE (12 gaussian kernels) and embedding guidance are shown in Figure 7. For each input image, we draw four samples for saturation fields from our conditional model. The diverse saturation adjustment results show that our model learns multimodal saturation distributions effectively. Our automatic saturation adjustment creates appealing photos. We demonstrate artistic stylization/editing by using our automated method.

Photo Relighting: In Figure 8, we show additional photo relighting results from our method. For each input image, we again draw four samples from the distribution. The photo relighting results show that our CDVAE model learns the light source distributions as well as important objects. Our model creates light fields coming from reasonable light sources and the lighting looks natural, especially on important objects.

6. Discussion

Our CDVAE generates good results qualitatively and quantitatively. However, there are still some limitations. Some of them are due to the limitations of VAE based generative models. For example, variational auto-encoders and its variants **oversmooth** their outputs, which leads to loss of spatial structure. Our multilayer gaussian latent variable

Figure 8. Input images in the first column are relighted with four samples from our CDVAE model. Since the images look natural, CDVAE has automatically learned the potential location of light sources, scene layouts and important objects. This information is critical for correct shading. There is typically no explicit supervision available for these parameters and we show it is not necessary, as CDVAE performs well without needing it. CDVAE learns this implicitly via raw-pixel relationships between albedo and shading. Our sampling creates diverse, yet natural relighted outputs. In the examples, light comes mainly from windows and sky, and objects are correctly relighted. (Figure best viewed in high resolution)

architecture can capture more complex structures, but we do miss out on the finer details compared to ground truth. Second, our model – like all current generative models – is applied to **low resolution** images, meaning that much of the structural and semantic information important to obtaining good results is lost. Last, our model has **no spatial hierarchy**. Coarse to fine multiscale hierarchy on both generative side and conditional side would likely enable us to produce results with more details.

7. Conclusion

We described an approach that simplifies building conditional models by building a joint model. Our joint model yields a conditional model that can be easily sampled. This allows us to train on scattered data using a joint model. We have demonstrated our approach on the task of generating photo-realistic relighted and resaturated images. We propose a metric regularization of code space which prevents code collapse. In future, this regularization can be investigated in the context of other generative models.

8. Appendix

8.1. Architecture Details

Our CDVAE has a different architecture compared to a CVAE. The detailed architecture of our CDVAE is in Table 8.1. Write l_{in} for the input layer and l_{out} for the output layer, fc stands for a fully connected layer, mean is the mean of the gaussian distribution of the code space, and var is the variance of the gaussian distribution of the code space. Sample is the process of sampling the gaussian distribution with mean and var. lout is sampled from mean4 and var_4 . We use L_2 regularization (or weight decay) for the parameters for MDN model. The learning rate is set to 5×10^{-5} and we use the ADAM optimizer. We initially set the reconstruction cost high, LPP embedding guidance cost high, and MDN cost low. We keep this setting and train for 100 epochs. For the next 200 epochs, we gradually decrease the embedding cost, and increase the MDN cost. Finally, we keep the relative cost fixed and train another 200 epochs.

8.2. DVAE

The difference between DVAE [16] and VAE [7] is multiple layers of gaussian latent variables. DVAE for x_c (same for x_g) consists of L layers of latent variables. To generate a sample from the model, we begin at the top-most layer (L) by drawing from a Gaussian distribution to get $z_{c,L}$.

$$P(z_{c,L}) = \mathcal{N}(z_{c,L}|0,I) \tag{8}$$

The mean and variance for the Gaussian distributions at any lower layer is formed by a non-linear transformation of the sample from above layer.

$$\mu_{c,i} = f_{\mu_{c,i}}(z_{c,i+1}) \tag{9}$$

$$\sigma_{c,i}^2 = f_{\sigma_{-i}^2}(z_{c,i+1}) \tag{10}$$

where f represents multi-layer perceptrons. We descend through the hierarchy by one hot vector sample process.

$$z_{c.i} = \mu_{c.i} + \xi_i \sigma_{c.i} \tag{11}$$

where ξ_i are mutually independent Gaussian variables. x_c is generated by sampling from the Gaussian distribution at the lowest layer.

$$P(x_c|z_{c,1}) = \mathcal{N}(x_c|\mu_{c,0}, \sigma_{c,0}^2)$$
 (12)

The joint probability distribution $P(x_c,z_c)$ of this model is formulated as

$$P(x_c, z_c) = P(x_c|z_{c,1})P(z_c)$$

$$= P(x_c|z_{c,1})P(z_{c,L}) \prod_{i=1}^{L-1} P(z_{c,i}|z_{c,i+1})$$
(13)

where $P(z_{c,i}|z_{c,i+1}) = \mathcal{N}(z_{c,i}|\mu_{c,i},\sigma_{c,i}^2)$. Other details of the DVAE model are similar to VAE.

8.2.1 Inference

DVAE with several layers of dependent stochastic variables are difficult to train which limits the improvements obtained using these highly expressive models. LVAE [20] recursively corrects the generative distribution by a data dependent approximate likelihood in a process resembling the recent Ladder Network. It utilizes a deeper more distributed hierarchy of latent variables and captures more complex structures. We follow this work and for x_c , write $\mu_{c,p,i}$ and $\sigma_{c,p,i}^2$ for the mean and variance on the i's level of generative side, write $\mu_{c,q,i}$ and $\sigma_{c,q,i}^2$ for the mean and variance on the i's level of inference side.

This changes the notation in the previous part on the generative side.

$$P_p(z_c) = P_p(z_{c,L}) \prod_{i=1}^{L-1} P_p(z_{c,i}|z_{c,i+1})$$
 (14)

$$P_p(z_{c,L}) = \mathcal{N}(z_{c,L}|0,I)$$
 (15)

$$P_p(z_{c,i}|z_{c,i+1}) = \mathcal{N}(z_{c,i}|\mu_{c,p,i},\sigma_{c,p,i}^2)$$
 (16)

$$P_p(x_c|z_{c,1}) = \mathcal{N}(x_c|\mu_{c,p,0}, \sigma_{c,p,0}^2)$$
 (17)

On the inference side, the notation also changes.

$$P_q(z_c|x_c) = P_q(z_{c,1}|x_c) \prod_{i=2}^{L} P_q(z_{c,i}|z_{c,i-1})$$
 (18)

$$P_q(z_{c,1}|x_c) = \mathcal{N}(z_{c,1}|\mu_{c,q,1}, \sigma_{c,q,1}^2)$$
 (19)

$$P_q(z_{c,i}|z_{c,i-1}) = \mathcal{N}(z_{c,i}|\mu_{c,q,i}, \sigma_{c,q,i}^2)$$
 (20)

During inference, first a deterministic upward pass computes the approximate distribution $\hat{\mu}_{c,q,i}$ and $\hat{\sigma}^2_{c,q,i}$. This is followed by a stochastic downward pass recursively computing both the approximate posterior and generative distributions.

$$P_q(z_c|x_c) = P_q(z_{c,L}|x_c) \prod_{i=1}^{L-1} P_q(z_{c,i}|z_{c,i+1})$$
 (21)

$$\sigma_{c,q,i} = \frac{1}{\hat{\sigma}_{c,q,i}^{-2} + \sigma_{c,p,i}^{-2}}$$
 (22)

$$\mu_{c,q,i} = \frac{\hat{\mu}_{c,q,i} \hat{\sigma}_{c,q,i}^{-2} + \mu_{c,p,i} \sigma_{c,p,i}^{-2}}{\hat{\sigma}_{c,q,i}^{-2} + \sigma_{c,p,i}^{-2}}$$
(23)

$$P_q(z_{c,i}|\cdot) = \mathcal{N}(z_{c,i}|\mu_{c,q,i}, \sigma_{c,q,i}^2)$$
 (24)

where $\mu_{c,q,L} = \hat{\mu}_{c,q,L}$ and $\sigma^2_{c,q,L} = \hat{\sigma}^2_{c,q,L}$.

Table 1. Details for the CDVAE architecture we proposed.

8.3. Joint Models

8.3.1 Separate DVAEs

From Section 3 in the paper, the joint probability $P(\boldsymbol{x}_c, \boldsymbol{x}_g)$ in CDVAE model is

$$P(x_c, x_g) = \int_z P(x_c|z_c) P(x_g|z_g) P(z_g, z_c) dz_g dz_c$$
 (25)

If
$$z_c$$
 and z_g are independent, so $P(z_g, z_c)$

First, we prove that if the joint probability is independent, we will get two separate DVAEs. Then, we prove the derivations for joint model with non-independent joint probability.

 $P(z_q)P(z_c)$, and Equation 25 can be transformed

$$P(x_c, x_g) = \int_z P(x_c|z_c) P(x_g|z_g) P(z_g) P(z_c) dz_g dz_c$$

$$= \int_z (P(x_c|z_c) P(z_c)) dz_c (P(x_g|z_g) P(z_g)) dz_g$$

$$= \int_{z_c} P(x_c|z_c) P(z_c) dz_c + \int_{z_g} P(x_g|z_g) P(z_g) dz_g$$

$$= P(x_c) + P(x_g)$$
(26)

where $P(x_c)$ is DVAE model for x_c and $P(x_g)$ is DVAE model for x_g .

8.3.2 Joint Model Derivation

From Section 2 in the paper, we have objective function for VAE as

$$VAE(\theta) = \sum_{data} \left[\mathbb{E}_Q \log P(x|z) - \mathbb{D}(Q||P(z)) \right]$$
 (27)

where Q = P(z|x). Applying the same derivations, the objective function for our CDVAE model can be written as

$$CDVAE(\theta_c, \theta_g) = \sum_{data} [\mathbb{E}_Q \log P(x_c, x_g | z_c, z_g) - \mathbb{D}(Q || P(z_c, z_g))]$$
(28)

where $Q=P(z_c,z_g|x_c,x_g)$. Assume it is possible to encode x_c without seeing x_g , then the variational distribution $Q=P(z_c|x_c)P(z_g|x_g)$ applies. It is also possible to decode x_c without seeing x_g , so we have $P(x_c,x_g|z_c,z_g)=P(x_c|z_c)P(x_g|z_g)$. With these formulas, Equation 28 can be transformed

$$\mathbb{E}_{Q} \log P(x_c, x_g | z_c, z_g) = \mathbb{E}_{Q} \log(P(x_c | z_c) P(x_g | z_g))$$

$$= \mathbb{E}_{Q_1} \log P(x_c | z_c)$$

$$+ \mathbb{E}_{Q_2} \log P(x_g | z_g)$$
(29)

where $Q_1=P(z_c|x_c)$ and $Q_2=P(z_g|x_g)$. The joint distribution can be written as $\log P(z_c,z_g)=\log P(z_c)+\log P(z_g)+F_{\mbox{mdn}}(z_c,z_g)$, so we have the following equations for the second part.

$$\mathbb{D}(Q||P(z_{c}, z_{g})) = \mathbb{D}(P(z_{c}|x_{c})P(z_{g}|x_{g})||P(z_{c}, z_{g}))
= \mathbb{E}_{Q}(\log(P(z_{c}|x_{c})P(z_{g}|x_{g})) - \log P(z_{c}, z_{g}))
= \mathbb{E}_{Q_{1}}(\log P(z_{c}|x_{c})) + \mathbb{E}_{Q_{2}}(\log P(z_{g}|x_{g}))
- \mathbb{E}_{Q_{1}}(\log P(z_{c})) - \mathbb{E}_{Q_{2}}(\log P(z_{g}))
- \mathbb{E}_{Q}(F_{\text{mdn}}(z_{c}, z_{g}))
= \mathbb{D}(Q_{1}||P(z_{c})) + \mathbb{D}(Q_{2}||P(z_{g}))
- \mathbb{E}_{Q}(F_{\text{mdn}}(z_{c}, z_{g}))$$
(30)

In our CDVAE model, we have $\log P(z_c) = -\frac{z_c^T z_c}{2}$ and $\log P(z_g) = -\frac{z_g^T z_g}{2}$ because z_c and z_g are Gaussian distributions. Our CDVAE objective function turns into

$$CDVAE(\theta_c, \theta_g) = DVAE(\theta_c) + DVAE(\theta_g) + \sum_{data} \mathbb{E}_Q(F_{\mathbf{mdn}}(z_c, z_g))$$
(31)

8.4. Embedding Influence

We compare the results with embedding guidance and without embedding guidance. The comparisons for reshading can be found in Figures 9. The re-shading results without embedding guidance tend to have less variety, more flaws and artifacts. The comparisons for re-saturation can be found in Figures 10. The re-saturation results without embedding guidance tend to have limited variety and produce less vivid results.

8.5. Quantitative Results

The detailed quantitative evaluation results for **photo relighting** are in Table 2 and **image resaturation** are in Table 3. The tables contain best error to ground-truth with different sample numbers. As the sample number increases, the error drops fast at beginning, and then becomes stable. Our CDVAEs are consistently better than other methods. The second parts of both tables are average variances across 100 samples. We only report the final variance, since it almost does not change with the sample number. The variance we report comes from 100 samples.

8.6. Qualitative Results

We include more qualitative results and comparisons in this section. **Photo relighting** results and comparisons can be found in Figure 11, 12. Photo relighting results with CGAN tend to have less variety and be less reasonable; results with CPixel tend to be extreme and random, and they also have less spatial structures; results with CVAE suffers from mode collapsion and have limited variety. **Image resaturation** results and comparisons can be found in Figure 13, 14. Image re-saturation results with CGAN tend to ignore the image content and like random, and creates various of artifacts; results with CPixel tend to be extreme, and either like random or go into mode collapsion; results with CVAE have limited variety and creates more artifacts.

	Best Error to Ground Truth					Variance
	Sample# 3	Sample# 10	Sample# 30	Sample# 60	Sample# 100	Sample#
NN	3.04	2.30	1.93	1.76	1.66	1.61
CVAE	2.07	1.83	1.68	1.60	1.56	0.19
CGAN	3.07	2.49	2.16	2.02	1.94	1.19
CPixel	3.06	2.32	1.91	1.74	1.59	1.92
$CDVAE_{noemb}$	2.78	2.19	1.82	1.66	1.57	1.39
CDVAE4	2.44	1.66	1.33	1.20	1.11	1.77
CDVAE12	2.49	1.69	1.33	1.20	1.12	1.74

Table 2. Photo relighting results. First part is best error to ground truth with different sample numbers; second part is variance, which is stable with different sample numbers. (all results need $\times 10^{-2}$)

	Best Error to Ground Truth					Variance
	Sample# 3	Sample# 10	Sample# 30	Sample# 60	Sample# 100	Sample#
NN	10.12	8.40	7.09	6.52	6.20	4.58
CVAE	6.73	5.59	4.93	4.53	4.25	1.20
CGAN	8.06	6.20	5.37	5.03	4.83	4.79
CPixel	7.94	6.43	5.94	5.51	5.29	4.34
$CDVAE_{noemb}$	7.08	5.74	4.95	4.57	4.32	1.53
MDN4	6.62	5.11	4.37	4.05	3.86	3.48
MDN12	6.40	5.04	4.33	4.02	3.82	3.55

Table 3. Image re-saturation results. First part is best error to ground truth with different sample numbers; second part is variance, which is stable with different sample numbers. (all results need $\times 10^{-2}$)

Figure 9. Comparisons to no embedding guidance for re-shading results (part 2). The re-shading results without embedding guidance tend to have less variety, more flaws and artifacts.

Figure 10. Comparisons to no embedding guidance for re-saturation results (part 1). The re-saturation results without embedding guidance tend to have limited variety and produce less vivid results.

Figure 11. Photo relighting results (part 1). Photo relighting results with CGAN tend to have less variety and be less reasonable; results with CPixel tend to be extreme and random, and they also have less spatial structures; results with CVAE suffers from mode collapsion and have limited variety.

Figure 12. Photo relighting results (part 3). Photo relighting results with CGAN tend to have less variety and be less reasonable; results with CPixel tend to be extreme and random, and they also have less spatial structures; results with CVAE suffers from mode collapsion and have limited variety.

Figure 13. Image re-saturation results (part 1). Image re-saturation results with CGAN tend to ignore the image content and like random, and creates various of artifacts; results with CPixel tend to be extreme, and either like random or go into mode collapsion; results with CVAE have limited variety and creates more artifacts.

Figure 14. Image re-saturation results (part 2). Image re-saturation results with CGAN tend to ignore the image content and like random, and creates various of artifacts; results with CPixel tend to be extreme, and either like random or go into mode collapsion; results with CVAE have limited variety and creates more artifacts.
