Abstract—Deep Neural Networks (DNNs) are being used to solve a wide range of problems in many domains including safety-critical domains like self-driving cars and medical imagery. DNNs suffer from vulnerability against adversarial attacks. In the past few years, numerous approaches have been proposed to tackle this problem by training networks using adversarial training. Almost all the approaches generate adversarial examples for the entire training dataset, thus increasing the training time drastically. We show that we can decrease the training time for any adversarial training algorithm by using only a subset of training data for adversarial training. To select the subset, we filter the adversarially-prone samples from the training data. We perform a simple adversarial attack on all training examples to filter this subset. In this attack, we add a small perturbation to each pixel and a few grid lines to the input image.

We perform adversarial training on the adversarially-prone subset and mix it with vanilla training performed on the entire dataset. Our results show that when our method-agnostic approach is plugged into FGSM [9], we achieve a speedup of 3.52x on MNIST and 1.98x on the CIFAR-10 dataset with comparable robust accuracy. We also test our approach on state-of-the-art Free adversarial training [24] and achieve a speedup of 1.2x in training time with a marginal drop in robust accuracy on the ImageNet dataset.

Index Terms—Adversarial Training, Adversarial Robustness, Adversarial attacks

I. INTRODUCTION

In the past few years, Deep Neural Networks (DNNs) have shown the state of the art performance on a wide range of domains like computer vision [2], reinforcement learning [56] and natural language processing [3]. DNNs are now being applied in various domains such as credit scoring [4], judicial system [1], self driving cars [5], and medical imagery [6]. Application in these domains requires DNNs to be trustworthy and dependable [7], [8].

On the other hand, DNNs offer poor robustness against adversarial attacks [9], [10]. A small, human imperceptible, perturbation in test input can easily fool the neural network and result in a significant change in the output of the network [11], [12], [55]. In a safety-critical application, the vulnerability against minor perturbations can be exploited by attackers to change the output significantly leading to catastrophic outcomes [8]. Recently, numerous approaches have been proposed to improve the robustness of DNNs using adversarial training, a technique in which a network is trained on adversarial examples [13]–[16]. Adversarial examples are small modifications to training input samples, which are carefully crafted to change model’s prediction.

Adversarial training can be classified into 2 types: untargeted and targeted. In untargeted adversarial training, the aim is to find a small perturbation for the input to misclassify it to any incorrect class like FGSM [9], Fast Gradient Value [17], universal adversarial perturbations [18], black-box attacks [19]. More recent techniques focus on target-specific adversarial training [14], [20]–[23]. Here the aim is to find a small perturbation that will change the output of the input image to a particular target class.

One of the main issues with most of the proposed methods for adversarial training is the increase in training time as pointed in [25], [26]. Adversarial training adds a lot of overhead to vanilla training and increases the training time by many folds. The initial approaches like FGSM [9] take around 8-9x more time (on datasets like CIFAR-10) when compared with vanilla training. This gigantic increase in training time makes adversarial training not feasible for many real-world problems and applications. The high computation cost of adversarial training has motivated a lot of work [24]–[26], [57]–[59], they aim to reduce the training time without compromising on the robustness accuracy.

All the proposed methods for decreasing the training time for adversarial methods performs optimisation on models [24]–[26]. In this paper, we are first to show that we do not need to perform adversarial attacks on the entire training data for adversarial training. We show that we can achieve similar performance by using only a fraction of training data for adversarial example generation, thus decreasing the training time drastically. We propose a method-agnostic approach where we mix adversarial training with vanilla training.

We perform a simple adversarial attack on all training samples, to filter the adversarially-prone subset from the training set. In this attack, we add a small perturbation to each pixel and a few grid lines to the input image. The adversarially-prone subset contains samples that are more prone to adversarial attacks than other samples in the training set. We perform adversarial training only on the adversarially-prone subset.

We perform extensive experiments on the famous, FGSM approach [9]. We show the performance on CIFAR-10 and MNIST datasets. By combining vanilla training with adversarial training on the adversarially-prone subset, we reach comparable robustness with 2 to 3.5 times faster training time. We also apply our approach to the state-of-the-art, Free adversarial training [24] method on the ImageNet dataset.

Fig. 1: A sequence showing effect of small perturbation to input image. (a)original image (b)every pixel value in input is modified by a random number between +30 to -30 (c)few random lines are added to the original image

We show a speedup of 1.2 times with decreasing the robust accuracy marginally by 1.68% on Free adversarial training.

Our main contributions in this paper are two-fold. First, we show that we do not need entire training dataset for adversarial training. Second, we propose a method to filter adversarially-prone subset of training data and perform adversarial training only on this subset. Our proposed approach speeds up training time for any adversarial training method and achieving comparable accuracy.

II. RELATED WORK

a) Adversarial Attacks and Training: Adversarial examples for deep neural networks were first discovered by [11]. One of the most popular adversarial attacks, FGSM [9] perturbs every input dimension but with a small quantity in the direction of the sign of the gradient. A lot of approaches have been proposed to generate adversarial attacks [13], [20], [27], [28], [31]. Some approaches work on changing a single pixel [33], while some make minimal modification to input image such as blurring [34], adding a small sub-network [37], spatial transformation [38]. Some attacks have show strong transferability of adversarial examples across neural network models [39]. In [34] authors show that approaches like simple blurring and modifying a single optimal pixel by a large amount are able to fool the network.

In [32] authors show that by modifying all pixels in the input image by a random number between 30 to 60, they were able to reduce confidence for 65.9% images and generate 44.7% misclassifications on different datasets. [17] provides a way to generate multiple perturbations for a single image. [18] provides an image-agnostic approach for generating perturbations. Some works have been proposed on evaluating the robustness against strong attacks [40]–[43]. Advances in adversarial attacks are complemented by advances in adversarial training [14], [16]. [44] uses high level features to guide the pixel denoiser, [45] proposed an approach that works with large datasets networks, [46] uses randomized smoothing, [47] uses training data distribution to perturb images.

Recent work on adversarial training aims at reducing the overhead added by training by adversarial examples [48]–[50]. [24] recycles gradient information during the model update for faster example generation, [25] uses random initialization to further speed up adversarial training. [26]

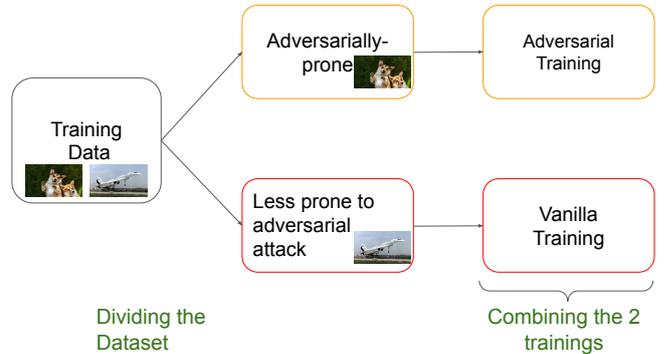

Fig. 2: Overview of our method. We first divide the training dataset into 2 parts based on susceptibility to adversarial attacks. Then we perform adversarial training only on adversarially-prone subset and combine it with vanilla training.

trains a feed-forward neural network in a self-supervised manner to generate adversarial examples.

b) Representing inputs as intervals: Interval analysis has been used in various different approaches. [51], [52] provides a certifiable robustness for small perturbations, [53] find adversarial perturbation by formulating it as mixed integer programming, [29], [30] used interval analysis to find tight bounds on DNN outputs for safety purposes. [54] used it to find minimum distortion in input to generate adversarial examples. In this work, we will be using input interval to filter adversarially prone examples from the training dataset.

III. METHOD

In this work, we refer to vanilla training as normal training without adversarial examples. Adversarially-prone samples are samples which are more prone to adversarial attacks as compared to other samples. We aim to find an adversarially-prone subset of training data. To achieve this, we use the concept of interval analysis as proposed by [29] to find a prediction range for each training sample.

Our method-agnostic approach can be used with any adversarial training method. We do not modify the way adversarial examples are being generated by the adversarial training method. Our approach proposes to perform adversarial training only on adversarially-prone subset rather than the entire training dataset. We combine vanilla training with adversarial training in a ratio of 2:1, thus performing adversarial training on every third iteration.

A. Filtering adversarially-prone data

[32] showed that perturbation of 60 pixels gives the best results for adversarial attacks. We used results from [32] to select the interval length of perturbation to be 60 pixels. This perturbation interval is used for filtering the adversarially-prone subset and each pixel in the input image is perturbed by a maximum of 60 pixels. For example, let's say that the original pixel value is x , the perturbation interval will be $[x-60, x+60]$. We aim to find the model prediction range for the image in this perturbation interval.

Our aim is to find the model prediction range across the perturbation interval with minimum computation required.

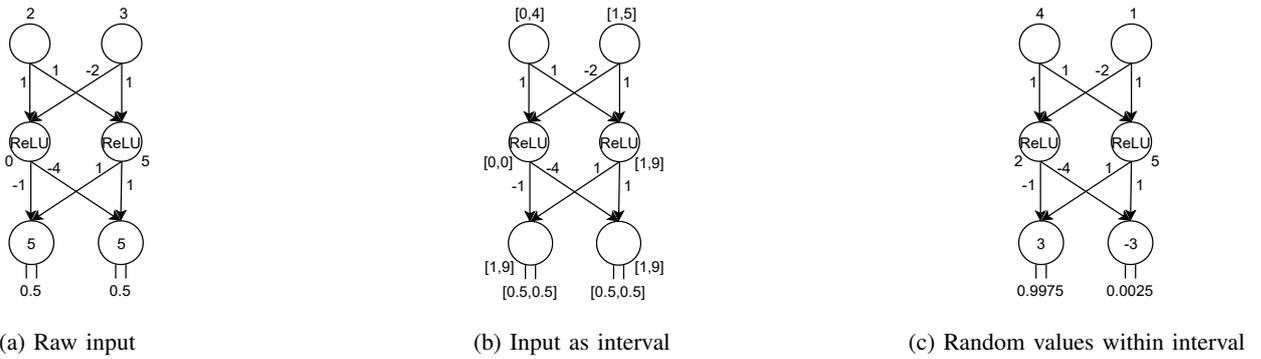

Fig. 3: Illustration showing (a) propagation of raw input to the network, (b) changing the input to have an interval of length 2 and propagating upper and lower bounds (0,1), (4,5) (c) propagating random values from the input interval. This shows that we can get extreme values of an output range for any random input within the input interval

Initial assumption would be that we can get prediction range by measuring model’s prediction at extreme ends of the prediction range. We show that this assumption is wrong and that extreme values of the prediction range can exist for any set of inputs.

Let us take the example of Figure 3. We have a single hidden layered neural network with ReLU activation function in the first layer and softmax at the last layer and weights of nodes are selected as shown in the figure. Propagation of inputs 2 and 3 through the network, produces an output of 0.5 for each class. Now let’s consider a perturbation of length 2 pixels. So now the inputs can be taken anywhere between [0,4] and [1,5] respectively. In figure 1(b), the lower and upper bounds of the perturbation interval are propagated i.e 0,1 and 4,5. The network outputs 0.5 for both these cases. In Figure 1(c), we select random value 4,1 for propagation. The network outputs 0.9975 for class 0 and 0.0025 for class 1. This shows that we can get extreme values for the prediction range for any set of inputs.

[34] shows that blurring the image changes model’s prediction for a lot of samples. [35] shows the importance of randomisation in adversarial attacks. [36] shows adding random lines in the image changes models prediction for majority of samples. All these approaches takes very less computation time and thus we use the works from [32], [34]–[36], to perform 2 types of adversarial attacks to determine the prediction range.

In the first attack, we perturb every pixel value by a random number between 0 and 60. In the second attack, we add single-pixel grid lines along the height and width at randomly selected rows and columns. We perform both these attacks on the input to get a prediction range. We choose these two attacks as they take very little computation time and result in a good adversarially-prone subset. We tried adding more attacks but they increased computation time with a small increase in the size of the adversarially-prone subset, so we decided to use these two attacks for our approach.

We perform these attacks 3 times to get a prediction range for each sample. As the model trains, the adversarial boundaries keep changing. To get the updated adversarially-prone subset, we filter this subset after every 4 epochs. Using the prediction

range, we filter samples based on the change in the highest probability prediction class across the prediction range. For the first type of attack, we select a random pixel value between -60 to +60 for each pixel. For the grid lines attacks, we select $\min(5, 0.05 \cdot \text{height})$ and $\min(5, 0.05 \cdot \text{width})$ as the number of grid lines for height and width respectively.

B. Combining adversarial and vanilla training

We combine adversarial training and vanilla training by performing these 2 training procedures alternatively. From our analysis, we found that using a ratio of 2:1 between vanilla and adversarial training gave us the optimal results. Thus we perform adversarial training on every 3rd iteration and vanilla training on the remaining iterations. This ensures that the models see a mix of normal training samples and adversarial examples generated by using the most adversarially prone sample from the dataset. This helps in decreasing the training time as compared to general adversarial training, with a marginal decrease in accuracy. More analysis on this can be found in the experiments section.

Our approach to select the adversarially-prone subset helps us to find the training samples that are close to the decision boundary of a class learned by the model. Performing a small perturbation in the input changes the predicted class for these samples. Thus for adversarial training, we want to use only the training samples which are close to the decision boundary and thus are more prone to adversarial attacks. This helps in decreasing the training time without affecting the model performance. Our proposed approach uses only about 30-40% of the training dataset for adversarial training.

Previous work which focus on improving training time [24], [26] does improvement on gradient update or way of training. To best of our knowledge, we are the first to propose using a subset of training set for adversarial training. When clubbed with other works on improving training time, our approach can further decrease the training time for any adversarial training method.

IV. EXPERIMENTS

In this section, we present experimental results of our novel strategy on 2 adversarial training algorithms : FGSM [9] and Free Adversarial training [24]. We show that we achieve comparable adversarial robustness, without changing the way

Method and dataset used	Training Procedure	Vanilla Acc	Robust Accuracy	Train Time	Improvement
FGSM [9] on MNIST	Adversarial	99.21	97.71	37.9 min	3.52
	Vanilla + Adv		98.71	10.8 min	
FGSM [9] on CIFAR-10	Adversarial	97.50	86.10	49.7 hr	1.98
	Vanilla + Adv		85.46	25.1 hr	
Free adv [24] on ImageNet	Adversarial	90.88	83.52	64.1 hr	1.20
	Vanilla + Adv		81.84	53.5 hr	

TABLE I: We show the results of using our proposed technique on adversarial training techniques such as FGSM [9] and Free adversarial training [24]. First we train networks using the adversarial training and then we mix vanilla and adversarial training. Robust accuracy is the accuracy of the trained model towards adversarial attacks. Last column shows speedup in training time by using our proposed method. We show speed-up in training time with marginal change in robust accuracy.

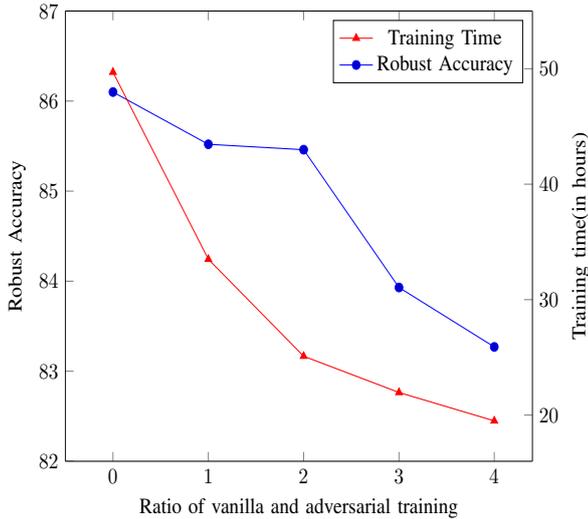

Fig. 4: Graph showing the tradeoff between robust accuracy and training time by changing ratio between vanilla and adversarial training on the CIFAR-10 dataset. As the proportion of vanilla training increases the training time decrease significantly while decreasing the robust accuracy marginally.

of generating adversarial attacks with a significant decrease in training time. To the best of our knowledge, we are the first to present an optimization approach that can be used with any adversarial training algorithm. So direct comparison with other methods is not possible at this point. Our proposed method can have slightly lower robust accuracy than using only adversarial training as shown on CIFAR-10 and ImageNet in Table I. Our method is useful in cases where significant decrease in training time is more useful a slight decrease in robust accuracy.

For our analysis, we evaluate accuracy of models on adversarial attacks. We use robust accuracy as the measurement metric. Robust accuracy is the accuracy of the trained model towards adversarial attacks. We also report vanilla accuracy on each dataset, which is the accuracy without adversarial training. This column in table I is just for comparing vanilla training with adversarial training. As expected the adversarial accuracy is lower than vanilla accuracy on every dataset.

A. Results on MNIST

We tested our approach on the MNIST dataset using FGSM adversarial training. In Table I we show the results of only adversarial training and our approach. For our experiments,

we used standard hyperparameters used by Madry [13]. During training the adversarial examples are constructed with $\epsilon = 0.3$ as suggested in [13]. During the test time, $\epsilon = 0.3$ is used to measure robust accuracy. Using our novel approach of combining adversarial training with vanilla training, we achieved a 3.52 speed up in training time, while increasing the robust accuracy marginally from 97.71% to 98.71%. We deduce that the robust accuracy increased on MNIST due to better adversarial example generation from the adversarially-prone subset.

B. Results on CIFAR-10

Next, we evaluated our approach on the CIFAR-10 dataset using FGSM adversarial training. We trained the CIFAR-10 model using Wide-Resnet 32-10 model and standard hyperparameters used by Madry *et al.* [13]. During training the adversarial examples are constructed with $\epsilon = 0.0157$ (4/255) as suggested by [13]. Same ϵ value is used to measure robust accuracy during test time. The results are shown in Table I. Conventional adversarial training on the CIFAR-10 dataset took around 50 hours to converge. By using our approach, we were able to decrease the training time by a factor of 1.98 and bring it down to 25 hours. The robust accuracy of the model decreased marginally by 0.64%. This shows that we were able to achieve a similar level of robustness by using a subset of training data. We propose that for tasks where training time ranges in days or weeks, our approach can be very effective. A speed of around 2 will result in saving days and weeks of training time and computation.

C. Results on Fast-adv

Next, we evaluated our approach on a state-of-the-art Free adversarial training algorithm [24] on the ImageNet dataset. We used the open-sourced code for Free adversarial training and performed experiments for 50 epochs on the ImageNet dataset. The value of $\epsilon = 2/255$ for adversarial example generation and testing. As shown in Table I, we achieved a speedup of 1.2x, thus decreasing the training time by more than 10 hours. The robust accuracy decreases marginally by 1.68% from 83.52 to 81.84. We report top5 precision accuracy on the test set. We deduce that training time decreased significantly as we save time on generating adversarial attacks on the entire training dataset and use only a subset of it for adversarial training. This shows that our approach can be applied to state-of-the-art adversarial training techniques and it will help in decreasing training time.

We performed the experiments four times to normalize the effect of randomness. The reported accuracy and training time are the average numbers for all experiments. We have performed all the experiments on CentOS. We used 2 and 4 NVIDIA Tesla V100 16GB GPUs for FGSM adversarial training on MNIST and CIFAR-10 datasets respectively. For Free adversarial training, we used 4 NVIDIA Tesla V100 16GB GPUs.

In Figure 4, we show the change in robust accuracy and training time with the change in the ratio of vanilla and adversarial training on CIFAR-10 dataset. A ratio of 0 is equivalent to performing only adversarial training, without mixing it with vanilla training. The training time decreases significantly as we increase the proportion of vanilla training. This is accompanied by a decrease in robust accuracy. We found that using a ratio of 2 gives the best tradeoff between robust accuracy and training time. This means that we perform adversarial training on every 3rd iteration on the adversarially-prone subset of training data.

V. CONCLUSION

Recent approaches in adversarial training have made great progress in improving the robustness of deep neural networks. Though improving the robustness of the model, adversarial training algorithms increase the computation time drastically. We show that we don't have to use the entire training dataset for adversarial training. Adversarial training, performed on most adversarially prone samples from the training dataset, can be combined with vanilla training to decrease the training time. Our approach can be plugged into any adversarial training algorithm. We show that after plugging in our approach, adversarial training algorithms have a speed of at least 1.2x, with a marginal drop in robust accuracy.
