We investigate the dynamical aspects of the quantum switch and find a particular form of quantum memory emerging out of the switch action. We first analyse the loss of information in a general quantum evolution subjected to a quantum switch and propose a measure to quantify the switch-induced memory. We then derive an uncertainty relation between information loss and switch-induced memory. We explicitly consider the example of depolarizing dynamics and show how it is affected by the action of a quantum switch. For a more detailed analysis, we consider both the control qubit and the final measurement on the control qubit as noisy and investigate the said uncertainty relation. Further, while deriving the Lindblad-type dynamics for the reduced operation of the switch action, we identify that the switch-induced memory actually leads to the emergence of non-Markovianity. Interestingly, we demonstrate that the emergent non-Markovianity can be explicitly attributed to the switch operation by comparing it with other standard measures of non-Markovianity. Our investigation thus paves the way forward to understanding the quantum switch as an emerging non-Markovian quantum memory.

I. INTRODUCTION

The superposition principle allows for multiple simultaneous evolutions, creating potential advantages in several quantum communication and quantum key distribution protocols by refining the effect of noise [1]. Usually, even in quantum scenarios, the information carriers or channels are arranged in well-defined classical configurations. However, with an external control system called the quantum switch (QS) [2], the causal order of multiple quantum evolutions or quantum channels can be put in superposition to create an *indefinite* causal order. For an illustration, let us consider two quantum channels, \mathcal{N}_1 and \mathcal{N}_2 , and a quantum state ρ . A control qubit determines the order of action of the two channels on ρ . When the control qubit is in the state $|0\rangle$, first \mathcal{N}_1 acts on ρ followed by \mathcal{N}_2 : $(\mathcal{N}_2 \circ \mathcal{N}_1)(\rho)$. The order is reversed when the control qubit is in the state $|1\rangle$, i.e., $(\mathcal{N}_1 \circ \mathcal{N}_2)(\rho)$. Hence, if the control qubit is prepared in the superposition state, $|+\rangle$ or $|-\rangle$ (where $|\pm\rangle \equiv (|0\rangle \pm |1\rangle)/\sqrt{2}$), we get a superposition of the causal orders of the actions of the two channels.

Indefiniteness in the order of quantum operations is beneficial over the standard quantum Shannon theory in several aspects. For example, it is better in testing the properties of quantum channels [3], winning non-local games [4], achieving quantum computational advantages [5], minimizing quantum communication complexity [6], improving quantum communication [7–9], enhancing the precision of quantum metrology [10], or providing thermodynamic advantages [11–14], etc. (also see [15, 16]). Recently, a second quantized Shannon theory has also been proposed [17]. Several of these advantages have already been ascertained in experiments [18–20]. Because of the enormous application potential, in the literature, more attention has been paid to the applicability of the QS in quantum information-theoretic and communication protocols and its advantages than its dynamical aspects. Here, however, we mainly focus on the dynamical aspects of the QS and find a form of quantum memory that emerges from the OS dynamics. This is important since quantum memory is crucial for future developments of quantum technologies in long-distance quantum communications [21, 22], enhancing the capacity of long quantum channels [23-26], or improving the efficiency of thermodynamic machines [27-29], etc. We also establish that the QS-induced memory (QSM) is equivalent to the non-Markovianity emerging from the resultant dynamics.

Since the past decade, quantum Non-Markovian processes are interpreted as a form of quantum memory in dynamical processes [30–48]. In the theory of open quantum systems [49], the system is generally assumed to couple weakly to a static environment without any memory of the past, leading to memoryless Markovian processes. This gives rise to a one-way information flow from the system to the environment. However, in realistic scenarios, such an ideal assumption does not hold, and, almost al-

[‡] subhadip.mitra@iiit.ac.in

[§] samyadeb.b@iiit.ac.in

ways, there is some non-Markovian backflow of information from the environment to the system. The backflow behaves like a memory providing advantages in information processing, communication and computational tasks over the memoryless or Markovian operations [26, 50-53]. There could be multiple reasons behind the occurrence of non-Markovianity, e.g., the strength of the systemenvironment interaction, the nature of the bath state, etc. Therefore, the system-environment interaction is one of the key resources for triggering such non-Markovian dynamics [33, 54-56]. Naturally, the QS also allows us to create and regulate the effect of non-Markovianity by manipulating the interaction between the environment and the system degrees of freedom via the control qubit. Hence, considering the control qubit to be a part of the environment, we can interpret that the emergent memory is stemming from a carefully controlled system-environment coupling. The ability to control memory effects by manipulating the system-environment interaction is beneficial in several information-processing tasks. For example, it creates potential advantages over classical technology [57–59], enhances the efficiencies of thermodynamic machines [27-29], preserves coherence and quantum correlation [60], allows the implementation of randomized benchmarking and error correction [61–63] or performing optimal dynamical decoupling [64, 65], etc.

In this paper, we investigate the dynamics of QS and characterize the non-Markovian memory emerging from it. We look at the information loss [66] in an ergodic Markovian-quantum evolution under the QS. The notion of ergodic quantum operations stems from the well-known ergodic hypothesis, according to which a system evolving under the influence of a static environment over a sufficiently long time will always evolve to a steady state, whose properties depend on the environment and the nature of the interaction. For example, in the case of thermal environments, the system will deterministically evolve to a thermal state with the same temperature as the environment. In quantum scenarios, it implies that ergodic quantum operations have a singular fixed point or, in other words, a particular steady state. For our purpose, we choose a generic Markovian operation satisfying the ergodicity property for the evolution operation on which a QS is applied.

The information loss at a time t can be measured by the difference of the geometric distances between two states at t and initially. Even though the difference never decreases with time for memoryless dynamics [66], it does so under a QS. This indicates a non-trivial relation between the information loss for a given dynamics under a QS and the QSM. We show that the sum of the information loss and the QSM is actually lower-bounded by the distance between the initial states. We consider a special case of the generalized Pauli channel (depolarizing channel) and investigate the dynamical evolution. We find that under the action of

QS, it allows reverse information transmission from the environment to the system. We prove that the informationcarrying capability of the completely depolarizing channel under QS is due to the induced non-Markovianity from the switch operation alone, and not due to the convex combination of two separate evolutions. For completeness, we also quantify the amount of noise a QS can tolerate. We introduce noise at both the control qubit and the final measurement on the control bit and investigate how the system evolutions get affected by the noises.

Further, we analyse non-Markovian quantum operations from their divisibility perspective [32]. Divisible quantum operations are those which can be perceived as a sequence of an arbitrary number of completely positive tracepreserving (CPTP) dynamical maps acting on a quantum system. Whereas, non-divisible operations elucidate the information backflow [31, 67], which can be perceived as a sufficient benchmark of the presence of non-Markovian memory in the concerning quantum operation.

The paper is organized as follows. In the next section, we briefly introduce the QS. In Section III, we evaluate the information loss of general quantum evolution with or without the QS, define the QSM measures and derive their relation. Further, we define the ergodic quantum channel formally and prove some relevant statements as a consolidated backdrop for our investigation. In section IV, we investigate the dynamical evolution under QS. We then explore how the QS behaves in the presence of various possible noises and investigate its tolerance against them. In section V, we derive a Lindbald-type master equation for qubit depolarizing dynamics subjected to QS and investigate how non-Markovianity emerges out of QS dynamics from the perspective of a qubit evolution. We then find interesting connections between the QS with some wellknown measures of non-Markovianity. Finally, in Section VI, we conclude and remark about possible future directions.

II. QUANTUM SWITCH

A quantum channel \mathscr{N} between systems A and B is a completely positive trace-preserving map from $L(\mathscr{H}_A)$ to $L(\mathscr{H}_B)$, where \mathscr{H}_A and \mathscr{H}_B are the Hilbert spaces corresponding to the input system A and the output system B, respectively, and $L(\mathscr{H}_i)$ are the set of bounded linear operators on \mathscr{H}_i . The action of \mathscr{N} on an input state $\rho \in L(\mathscr{H}_A)$ can be expressed in the Kraus representation (operatorsum representation) form as $\mathscr{N}(\rho) = \sum_i K_i \rho K_i^{\dagger}$, where $\{K_i\}$ are the Kraus operators for \mathscr{N} . If there are two channels, \mathscr{N}_1 and \mathscr{N}_2 , they can act either in parallel or in series. The parallel action of the channels can be realized as $\mathscr{N}_1 \otimes \mathscr{N}_2$. The series actions can be realized in more than one way: \mathscr{N}_1 followed by \mathscr{N}_2 (denoted by $\mathscr{N}_2 \circ \mathscr{N}_1$) or \mathscr{N}_2 followed

FIG. 1. The quantum switch. When the control qubit ω_c is prepared in $|0\rangle\langle 0|$ state, the state ρ can evolve first through channel \mathscr{N}_1 and then through \mathscr{N}_2 (the blue solid line) and when the control qubit is prepared in $|1\rangle\langle 1|$ state, the state ρ can evolve first through channel \mathscr{N}_2 and then through \mathscr{N}_1 (the orange dotted line). However, when the control qubit is prepared in $|+\rangle\langle +|$ state, the order of the action of two channels is in superposition. Finally, the control qubit is measured in $\{|\pm\rangle\langle\pm|\}$ basis.

by \mathcal{N}_1 (denoted by $\mathcal{N}_1 \circ \mathcal{N}_2$). If the causal order is definite, then among these two possibilities, any one of either $\mathcal{N}_2 \circ \mathcal{N}_1$ or $\mathcal{N}_1 \circ \mathcal{N}_2$ is allowed. However, as mentioned in the Introduction, the order of the action of two channels can be made indefinite with an additional ancillary system called the control qubit (ω_c) [7–9]. When ω_c is initialized in the $|0\rangle \langle 0|$ state, the $\mathcal{N}_2 \circ \mathcal{N}_1$ configuration acts on the state ρ , whereas the $\mathcal{N}_1 \circ \mathcal{N}_2$ configuration acts when ω_c is initialized in the $|1\rangle \langle 1|$ state. If $K_i^{(1)}$ represents the Kraus operator for \mathcal{N}_1 and $K_j^{(2)}$ for \mathcal{N}_2 , the general Kraus operator can be represented as

$$S_{ij} = K_j^{(2)} \circ K_i^{(1)} \otimes |0\rangle_{\alpha} \langle 0| + K_i^{(1)} \circ K_j^{(2)} \otimes |1\rangle_{\alpha} \langle 1|.$$
 (1)

The overall evolution of the combined system can be written as

$$S(\mathcal{N}_1, \mathcal{N}_2)(\boldsymbol{\rho} \otimes \boldsymbol{\omega}_c) = \sum_{i,j} S_{ij}(\boldsymbol{\rho} \otimes \boldsymbol{\omega}_c) S_{ij}^{\dagger}.$$
 (2)

In the end, the control qubit is measured on the coherent basis $\{|+\rangle\langle+|,|-\rangle\langle-|\}$. Then, for each outcome, the reduced state corresponding to the target qubit becomes,

$$_{c}\langle \pm | S(\mathcal{N}_{1}, \mathcal{N}_{2})(\boldsymbol{\rho} \otimes \boldsymbol{\omega}_{c}) | \pm \rangle_{c}.$$
(3)

This is essentially how the QS works, as we show schematically in Fig. 1.

III. INFORMATION LOSS AND THE MEASURE OF QUANTUM SWITCH

Before proceeding further, we need to introduce some basic concepts, like the notion of time-averaged quantum states and ergodic evolution, to understand the relationship between information loss and the QSM. The ergodic hypothesis of statistical mechanics states that if a physical system (be it classical or quantum) evolves over a long period, the time-averaged state of the system will be equal to its thermal state with a temperature equal to that of the bath, with which the system was interacting. In other words, for an observable f, if the (long-)time average $\langle f \rangle_t$ is equal to the ensemble average $\langle f \rangle_{ens}$ over the equilibrium state, the system is ergodic. If a quantum operation $\Phi_t(\cdot)$ acts on a state ρ from t = 0 to t = T, we can express the long-time-averaged state as

$$\overline{\Phi_{\infty}(\rho)} = \lim_{T \to \infty} \frac{1}{T} \int_0^T \Phi_t(\rho) \, dt. \tag{4}$$

Long-time averaging of any observable can thus be defined in the Schrödinger picture as

$$\langle f \rangle_{\infty} = \lim_{T \to \infty} \frac{1}{T} \int_{0}^{T} \operatorname{Tr} \left[f \Phi_{t}(\rho) \right] dt$$

$$= \operatorname{Tr} \left[f \left(\lim_{T \to \infty} \frac{\int_{0}^{T} \Phi_{t}(\rho) dt}{T} \right) \right]$$

$$= \operatorname{Tr} \left[f \overline{\Phi_{\infty}(\rho)} \right].$$
(5)

We now define the ergodic evolution as follows [66, 68].

■ **Definition 1:** A quantum evolution is ergodic if it has a singular fixed point and the time-averaged state equals that fixed point.

A dynamics or quantum evolution is said to possess a singular fixed point if there exists exactly one state that remains unaffected by the quantum evolution—for example, a depolarizing channel with the maximally mixed state, a thermal channel with the thermal state, an amplitude damping channel with the ground state, etc. Thus, if τ is the singular fixed point of a given quantum channel $\Phi_t(\cdot)$, i.e., if $\Phi_t(\tau) = \tau$, the channel is called ergodic if $\overline{\Phi_{\infty}(\rho)} = \tau$ for an arbitrary initial state ρ . We denote such channels as $\Phi_t^{\varepsilon}(\cdot)$. In Appendix A, we present an example of a qubit ergodic Pauli channel, which is relevant to our study. Note that, by definition, ergodic quantum channels are the true *memoryless* channels since the time-averaged states do not depend on the initial state at all.

For some channels, the singular fixed point τ remains unaltered even under the action of a QS. If we denote the action of such channels as $\Phi_t^S(.)$, then $\Phi_t^S(\tau) = \tau$. Below, we prove that such a condition is true even for generalized Pauli channels in arbitrary dimensions.

■ **Statement 1:** For generalized Pauli channels in arbitrary dimensions, their singular fixed point (maximally mixed state) remains unchanged under the action of the quantum switch.

Proof. The generalized Pauli channel for a *d*-dimensional quantum system can be represented by the following map [69],

$$\Lambda_W(\rho) = \sum_{k,l=0}^{d-1} p_{kl} W_{kl} \rho W_{kl}^{\dagger}$$
(6)

where $W_{kl} = \sum_{m=0}^{d-1} \omega^{mk} |m\rangle \langle m+l|$ with $\omega = e^{2\pi i/d}$ are the unitary Weyl operators. The Weyl operators satisfy the following well-known properties:

$$W_{kl}W_{rs} = \boldsymbol{\omega}^{ks}W_{k+r,l+s}$$
 and $W_{kl}^{\dagger} = \boldsymbol{\omega}^{kl}W_{-k,-l}$ (7)

where the indices are modulo-*d* integers. For such channels, the maximally mixed state $\frac{\mathbb{I}}{d}$ is the fixed point. We show that the maximally mixed state remains the fixed point after the action of the QS. The reduced representation of the action of the QS over a generalized Pauli channel can be written as

$$\Lambda_{W}^{S}(\rho) = \frac{\sum_{k,l,r,s} \widetilde{W}_{klrs} \rho \widetilde{W}_{klrs}^{\dagger}}{\operatorname{Tr}\left[\rho \sum_{k,l,r,s} \widetilde{W}_{klrs}^{\dagger} \widetilde{W}_{klrs}\right]},$$
(8)

with $\widetilde{W}_{klrs} = \frac{\sqrt{p_{kl}p_{rs}}}{2} (W_{kl}W_{rs} + W_{rs}W_{kl})$ (see Appendix B).

Using these relations and the properties of dummy indices k, l, r, s, we get

$$\sum_{k,l,r,s} \widetilde{W}_{klrs} \frac{\mathbb{I}}{d} \widetilde{W}^{\dagger}_{klrs} = \frac{1}{d} \sum_{k,l,r,s} \widetilde{W}_{klrs} \widetilde{W}^{\dagger}_{klrs}$$
$$= \frac{1}{2d} \sum_{k,l,r,s} p_{kl} p_{rs} (1 + \omega^{ks - rl}) \mathbb{I}.$$
(9)

Therefore,

$$\Lambda_W^S\left(\frac{\mathbb{I}}{d}\right) = \frac{\frac{1}{d}\sum_{k,l,r,s} p_{kl} p_{rs}(1+\boldsymbol{\omega}^{ks-rl})\mathbb{I}}{\sum_{k,l,r,s} p_{kl} p_{rs}(1+\boldsymbol{\omega}^{ks-rl})} = \frac{\mathbb{I}}{d},$$
 (10)

which proves the statement.

We use the ergodic generalized Pauli channel in our further analysis.

A. Uncertainty relation between QS-induced memory and information loss

Let $D(\rho_1, \rho_2)$ be the geometric distance between two states ρ_1 and ρ_2 satisfying the necessary properties of a distance measure, i.e., it is symmetric, non-negative and obeys the triangular inequality. In particular, if $D(\rho_1, \rho_2)$ is the trace distance measure then $D(\rho_1, \rho_2) \equiv \frac{1}{2} ||\rho_1 - \rho_2||_1$, where $||A||_1 = \text{Tr}[\sqrt{A^{\dagger}A}]$. Now, under any noisy evolution Φ_t , the distance between two states can never increase where the final distance depends on the nature of the evolution. With this in mind, we define the following quantity.

Definition 2: If $\rho_1(0)$ and $\rho_2(0)$ are two initial states evolving under $\Phi_t(\cdot)$, the quantity $\Delta \mathscr{I}(\rho_1(t), \rho_2(t))$, defined as

$$\Delta \mathscr{I}(\rho_1(t), \rho_2(t)) \equiv D(\rho_1(0), \rho_2(0)) - D(\Phi_t(\rho_1(0)), \Phi_t(\rho_2(0))), \quad (11)$$

is a measure of the *information loss* across the channel.

The quantity $\Delta \mathscr{I}(\rho_1(t), \rho_2(t))$ quantifies the difference between the initial distinguishability of the two states and their distinguishability after the action of the noisy evolution Φ_t . If we consider an ergodic operation $\Phi_t^{\varepsilon}(\cdot)$ with a singular fixed point τ and take $\rho_1(0) = \rho$ and $\rho_2(0) = \tau$ then the information loss becomes

$$\Delta \mathscr{I}_{\varepsilon}(\boldsymbol{\rho}(t)) = D(\boldsymbol{\rho}, \tau) - D(\Phi_t^{\varepsilon}(\boldsymbol{\rho}), \tau),$$

since τ remains unaffected by the evolution. To make the measure state independent, we can optimize over the initial state ρ and define the measure as

$$\Delta \mathscr{I}^{M}_{\varepsilon}(\rho(t)) = \max_{\rho} \left[D(\rho, \tau) - D(\Phi^{\varepsilon}_{t}(\rho), \tau) \right].$$
(12)

Now, if τ is also a fixed point under QS, then the information loss under the QS dynamics will be

$$\Delta \mathscr{I}_{\mathcal{S}}(\boldsymbol{\rho}(t)) = D(\boldsymbol{\rho}, \tau) - D(\Phi_t^{\mathcal{S}}(\boldsymbol{\rho}), \tau),$$

and the state-independent maximized measure will be

$$\Delta \mathscr{I}_{S}^{M}(\rho(t)) = \max_{\rho} \left[D(\rho, \tau) - D(\Phi_{t}^{S}(\rho), \tau) \right].$$
(13)

We can now define the QS-induced memory as follows.

Definition 3: The *QS-induced memory* (QSM), \mathcal{Q}_s , can be defined as

$$\mathscr{Q}_{S}(t) \equiv D(\Phi_{t}^{S}(\rho), \Phi_{t}^{\varepsilon}(\rho)).$$

and the corresponding state-independent optimized QSM as

$$\mathscr{Q}_{S}^{M}(t) \equiv \max_{\rho} \left[D(\Phi_{t}^{S}(\rho), \Phi_{t}^{\varepsilon}(\rho)) \right].$$
(14)

Clearly, when the evolution $\Phi(\cdot)$ is unaffected by the switch, $\Phi_t^S = \Phi_t^{\varepsilon}$ and hence \mathcal{Q}_S will be zero.

We can relate $\Delta \mathscr{I}_{S}(\rho(t))$ with $\Delta \mathscr{I}_{\varepsilon}(\rho(t))$ as

$$\begin{split} \Delta \mathscr{I}_{S}(\rho(t)) &= D(\rho, \tau) - D(\Phi_{t}^{S}(\rho), \tau) \\ &= D(\rho, \tau) - D(\Phi_{t}^{S}(\rho) - \Phi_{t}^{\varepsilon}(\rho), \tau - \Phi_{t}^{\varepsilon}(\rho)) \\ &\geq D(\rho, \tau) - D(\Phi_{t}^{S}(\rho), \Phi_{t}^{\varepsilon}(\rho)) - D(\Phi_{t}^{\varepsilon}(\rho), \tau) \\ &\geq D(\rho, \tau) - \mathscr{Q}_{S}(t) - D(\Phi_{t}^{\varepsilon}(\rho), \tau), \end{split}$$

FIG. 2. In this figure, we consider the quantum states as elements of a vector space. The states $\vec{\rho}$, $\vec{\tau}$, $\vec{\Phi}_t^{\varepsilon}(\rho)$, and $\vec{\Phi}_t^{S}(\rho)$ are described in the text.

which implies,

$$\Delta \mathscr{I}_{S}(\boldsymbol{\rho}(t)) + \mathscr{Q}_{S}(t) \ge \Delta \mathscr{I}_{\varepsilon}(\boldsymbol{\rho}(t)). \tag{15}$$

Here, we have used the triangle inequality: $D(A,B) + D(B,C) \ge D(C,A)$ and the symmetric property of the distance measure: D(A,B) = D(B,A). The uncertainty relation between the information loss and the QSM in Eq. (15) is one of the main results of this paper. We will refer to it as the quantum switch-induced information inequality (QSI) later.

If we evaluate these measures for the time-averaged states under the QS, the information loss and the QSM measure reduce to

$$\Delta \overline{\mathscr{I}}_{S} = D(\rho, \tau) - D(\overline{\Phi_{\infty}^{S}(\rho)}, \tau)$$
(16)

and

$$\overline{\mathscr{Q}}_{S} = D(\overline{\Phi_{\infty}^{S}(\rho)}, \overline{\Phi_{\infty}^{\varepsilon}(\rho)}) = D(\overline{\Phi_{\infty}^{S}(\rho)}, \tau), \quad (17)$$

respectively, and the QSI in Eq. (15) reduces to an equality:

$$\Delta \overline{\mathscr{I}}_{S} + \overline{\mathscr{Q}}_{S} = D(\rho, \tau) = \Delta \overline{\mathscr{I}}_{\varepsilon}.$$
 (18)

The above equation indicates that as the QSM increases, the information loss decreases and hence, the QS is a resource for information storage undergoing noisy quantum operations.

The relation in Eq. (15) can also be understood from the pictorial representation in Fig. 2. From the triangle law, we

get

$$\begin{bmatrix} \overrightarrow{\tau} - \overrightarrow{\Phi}_{t}^{\varepsilon}(\rho) \end{bmatrix} + \begin{bmatrix} \overrightarrow{\Phi}_{t}^{S}(\rho) - \overrightarrow{\Phi}_{t}^{\varepsilon}(\rho) \end{bmatrix} = \begin{bmatrix} \overrightarrow{\tau} - \overrightarrow{\Phi}_{t}^{S}(\rho) \end{bmatrix}$$
$$\implies D(\Phi_{t}^{\varepsilon}(\rho) - \tau) + D(\Phi_{t}^{S}(\rho) - \Phi_{t}^{\varepsilon}(\rho)) \ge D(\Phi_{t}^{S}(\rho) - \tau)$$
$$\implies D(\rho, \tau) - D(\Phi_{t}^{S}(\rho), \tau) + D(\Phi_{t}^{S}(\rho), \Phi_{t}^{\varepsilon}(\rho))$$
$$\ge D(\rho, \tau) - D(\Phi_{t}^{\varepsilon}(\rho), \tau), \tag{19}$$

which implies Eq. (15). Now, let ρ^* be the initial state that maximizes the RHS, i.e., $\Delta \mathscr{I}^M_{\varepsilon}(t) = D(\rho^*, \tau) - D(\Phi^{\varepsilon}_t(\rho^*), \tau)$. Since Eq. (15) holds for the evolution from ρ^* as well, we have

$$\begin{split} [\Delta \mathscr{I}_{\mathcal{S}}(\boldsymbol{\rho}(t)) &+ \mathscr{Q}_{\mathcal{S}}(t)]_{\boldsymbol{\rho}(0) = \boldsymbol{\rho} \ast} \\ &= D(\boldsymbol{\rho}^{\ast}, \tau) - D(\Phi_{t}^{\mathcal{S}}(\boldsymbol{\rho}^{\ast}), \tau) + D(\Phi_{t}^{\mathcal{S}}(\boldsymbol{\rho}^{\ast}), \Phi_{t}^{\varepsilon}(\boldsymbol{\rho}^{\ast})) \\ &\geq \Delta \mathscr{I}_{\varepsilon}^{M}(t). \end{split}$$
(20)

Now, since $\Delta \mathscr{I}_S^M(t) \ge \Delta \mathscr{I}_S(t)$ and $\mathscr{Q}_S^M(t) \ge \mathscr{Q}_S(t)$, the uncertainty relation in Eq. (15) is naturally extended for the maximized state-independent measures:

$$\Delta \mathscr{I}_{S}^{M}(t) + \mathscr{Q}_{S}^{M}(t) \ge \Delta \mathscr{I}_{\varepsilon}^{M}(t).$$
(21)

IV. DYNAMICAL EVOLUTION UNDER THE ACTION OF QUANTUM SWITCH AND EMERGENCE OF NON-MARKOVIANITY

In this section, we study an explicit example of dynamical evolution and investigate how the evolution changes under the action of the QS. We analyse the QSM (1) from the perspective of non-Markovianity by deriving the Lindbladtype generator for the switch operation and (2) from the point of view of non-ergodicity as proposed in the previous section. For this purpose, we consider qubit depolarizing operation as described below.

A. Evolution under completely depolarizing dynamics in a definite causal structure

We choose the Markovian qubit-depolarizing channel for the case study. We call a channel Markovian if it is completely positive (CP) divisible. A dynamical map $\Phi_{(t,t_0)}$ is said to be CP divisible if it can be represented as $\Phi_{(t,t_0)} = \Phi_{(t,t_s)} \circ \Phi_{(t_s,t_0)}$, $\forall t_s$ with $t_0 \leq t_s \leq t$ and $\Phi_{(t,t_s)}$ is completely positive. The notation $\Phi_{(t,t_s)}$ means the quantum channel $\Phi(\cdot)$ acts for the time period t_s to t. When $t_0 = 0$, we abbreviate the notation as Φ_t , as in the previous section. Note that there are various other criteria for identifying quantum non-Markovianity in the literature, of which information backflow [31, 67] is relevant for our discussion. Information backflow is the reverse information flow from the environment to the system, mathematically quantified by the anomalous non-monotonic behaviours of known monotones (like the trace distance between two states) under dynamical evolution [31]. It is well-known that breaking CP-divisibility is a necessary condition for information backflow, but not vice versa.

We consider a CP-divisible map Φ_t possessing a Lindbladtype generator \mathscr{L}_t , i.e., $\Phi_t \equiv \exp(\int_0^t \mathscr{L}_s ds)$. The generator of the dynamics can be expressed as,

$$\frac{d}{dt}\boldsymbol{\rho}(t) = \mathscr{L}_t(\boldsymbol{\rho}(t)), \qquad (22)$$

where

$$\mathscr{L}_{t}(X) = \sum_{i} \Gamma_{i}(t) \left(A_{i} X A_{i}^{\dagger} - \frac{1}{2} \left\{ A_{i}^{\dagger} A_{i}, X \right\} \right)$$

with $\Gamma_i(t)$ being the Lindblad coefficients and A_i , the Lindblad operators. The necessary and sufficient condition for an operation being CP divisible is that all the Lindblad coefficients $\Gamma_i(t)$ are positive $\forall (i,t)$ [70, 71]. For our purpose, the evolution of a system under definite causal order is considered to be Markovian.

Starting with a definite causal order, we consider the following master equation,

$$\frac{d}{dt}\boldsymbol{\rho}(t) = \sum_{i=1}^{3} \gamma_i(t) \left[\boldsymbol{\sigma}_i \boldsymbol{\rho}(t) \boldsymbol{\sigma}_i - \boldsymbol{\rho}(t) \right]$$
(23)

where $\gamma_i(t)$ are the Lindblad coefficients and σ_i are the Pauli matrices. The qubit is represented by

$$\Phi_t(\rho) \equiv \rho(t) = \begin{pmatrix} \rho_{11}(t) & \rho_{12}(t) \\ \rho_{21}(t) & \rho_{22}(t) \end{pmatrix}.$$
 (24)

For the completely depolarizing channel, the corresponding dynamics are represented by a CP trace-preserving dynamical map,

$$\rho_{11}(t) = \rho_{11}(0) \left(\frac{1 + e^{-2\xi_1(t)}}{2} \right) + \rho_{22}(0) \left(\frac{1 - e^{-2\xi_1(t)}}{2} \right),$$

$$\rho_{22}(t) = 1 - \rho_{11}(t), \quad \rho_{12/21}(t) = \rho_{12/21}(0)e^{-2\xi_2(t)}, \quad (25)$$

with

$$\xi_1(t) = \int_0^t [\gamma_1(s) + \gamma_2(s)] ds \quad \text{and}$$

$$\xi_2(t) = \int_0^t [\gamma_2(s) + \gamma_3(s)] ds.$$

The corresponding Kraus operators are given by,

$$\begin{split} K_{1} &= \sqrt{A_{2}(t)} \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \quad K_{2} &= \sqrt{A_{2}(t)} \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}, \\ K_{3} &= \sqrt{\frac{A_{1}(t) + A_{3}(t)}{2}} \begin{pmatrix} e^{i\theta(t)} & 0 \\ 0 & 1 \end{pmatrix}, \\ K_{4} &= \sqrt{\frac{A_{1}(t) - A_{3}(t)}{2}} \begin{pmatrix} -e^{i\theta(t)} & 0 \\ 0 & 1 \end{pmatrix}, \end{split}$$
(26)

where,

$$A_{1}(t) = \frac{1 + e^{-2\tilde{\xi}_{1}(t)}}{2}, \quad A_{2}(t) = \frac{1 - e^{-2\tilde{\xi}_{1}(t)}}{2},$$
$$A_{3}(t) = e^{-2\tilde{\xi}_{2}(t)}, \quad \theta(t) = \tan^{-1}\left(\frac{\operatorname{Im} A_{3}(t)}{\operatorname{Re} A_{3}(t)}\right) = 0$$

Notice that the evolution is Markovian for the simple choice of the Lindblad coefficients, $\gamma_1(t) = \gamma_2(t) = \gamma_3(t) = \gamma > 0$. Unless stated otherwise, we choose this set of Lindblad coefficients throughout the paper.

B. Evolution under quantum switch

To see how the states evolve under the QS, we prepare two dynamical maps and put them in a superposition of causal orders with an additional control qubit, initially prepared in the $|+\rangle_{cc}\langle+|$ state. We consider both channels to be the same depolarizing channel, i.e., $\mathcal{N}_1 = \mathcal{N}_2 = \mathcal{E}$. In general, the control qubit can be measured in any coherent basis but, for our purpose, we measure it in the $\{|\pm\rangle_{cc}\langle\pm|\}$ basis. After measuring, the state ρ corresponding to the '+' outcome can be expressed as

$$\Phi_{t}^{S}(\rho) = \frac{1}{\mathscr{A}_{1}} c \langle +|S(\rho \otimes |+\rangle_{cc} \langle +|)|+\rangle_{c} \\ = \begin{pmatrix} A(t)\rho_{11}(0) + B(t)\rho_{22}(0) & C(t)\rho_{12}(0) \\ C(t)\rho_{21}(0) & B(t)\rho_{11}(0) + A(t)\rho_{22}(0) \end{pmatrix},$$
(27)

such that A(t) = (1 + C(t))/2, B(t) = (1 - C(t))/2, and

$$C(t) = \frac{\mathscr{G}^2 - 2\mathscr{G} + 9}{5\mathscr{G}^2 + 6\mathscr{G} - 3},$$

with $\mathscr{G} = e^{4\gamma t}$. Here, \mathscr{A}_1 is the normalization factor and the suffix 'c' represents the control qubit. In Fig. 3, we demonstrate the validity of the QSI in Eq. (15) for different values of γ . It proves the concerned QS dynamics obeys QSI perfectly. Moreover, the figure shows that initially the expression is driven away from the equality, but as time passes and the dynamics approaches the steady state, equality is reached. This, in turn, validates the equality of Eq. (18) for the long-time-averaged states. Below, we investigate the validity of this QSI for a more general situation of QS with arbitrary qubit control and measurement.

C. QSI for noisy quantum switches

We consider two different ways noise can be introduced to the QS. In the first case, the noise is quantum while in the second case, the noise is classical. By quantum noise, we mean that for the control qubit, an arbitrary pure state

FIG. 3. In this plot we verify the QSI in Eq. (15) for the stated qubit dynamics. The uncertainty deviation i.e, the difference between the left-hand side (LHS) and the right-hand side (RHS) of Eq. (15) for $\rho = |1\rangle \langle 1|$ for different values of γ are plotted. The difference $[= \Delta \mathscr{I}_S(\rho(t)) + \mathscr{Q}_S(t) - \Delta \mathscr{I}_{\varepsilon}(\rho(t))]$ increases initially but comes down to zero to settle there. As expected from the inequality relation, it is never negative.

is used instead of the $|+\rangle$ state and for the measurement, another arbitrary pure state is used in the place of $|+\rangle\langle+|$. For the case of the classical noise, we consider a mixed state in the $|\pm\rangle$ basis as the control and an arbitrary positive operator-valued measure (POVM) on the same basis. Note that here our goal is to evaluate the noise tolerance of the quantum switch itself. Hence, we introduce the noise directly to the switching process (which essentially involves preparing the control qubit and conducting the final measurement on the control qubit), irrespective of the nature of the channels upon which it operates.

However, before that, it is necessary to understand whether the QSI is valid for these general situations. For that, we need to verify **Statement 1** for such a generalized QS evolution. In Appendix C, we prove it for such a general consideration with an arbitrary control qubit and final measurement. We show that for the generalized Pauli channel, the fixed point remains unchanged under the QS operation. This is the only prerequisite for the validity of Eqs. (15) and (18) and hence it asserts that QSI is perfectly legible for the following considerations.

1. Quantum noise

The control qubit is prepared in the state, $\omega_c = \sqrt{p}|0\rangle + \sqrt{(1-p)}|1\rangle$ and the measurement on the control system

is performed in the $\{|\mathcal{M}_q\rangle \langle \mathcal{M}_q|, \mathbb{I} - |\mathcal{M}_q\rangle \langle \mathcal{M}_q|\}$ basis with $|\mathcal{M}_q\rangle = \sqrt{q}|0\rangle + \sqrt{(1-q)}|1\rangle$, with p, q being arbitrary probabilities. After the measurement, the state of the generic target system corresponding to the '+' outcome becomes

$$\Phi_{t}^{S}(\rho) = \frac{1}{\mathscr{A}_{2}c} \left\langle \mathscr{M}_{q} \left| S(\rho \otimes \omega_{c}) \right| \mathscr{M}_{q} \right\rangle_{c} \\ = \left(\begin{array}{c} A_{pq}(t)\rho_{11}(0) + B_{pq}(t)\rho_{22}(0) & C_{pq}(t)\rho_{12}(0) \\ C_{pq}(t)\rho_{21} & B_{pq}(t)\rho_{11}(0) + A_{pq}(t)\rho_{22}(0) \end{array} \right)$$
(28)

with $A_{pq}(t) = (1 + C_{pq}(t))/2$, $B_{pq}(t) = (1 - C_{pq}(t))/2$, and

$$C_{pq}(t) = \frac{f_p f_q (\mathscr{G}^2 - 2\mathscr{G} + 5) + p(4q - 2) + 2(1 - q)}{f_p f_q (\mathscr{G}^2 + 6\mathscr{G} - 3) + p(4q - 2)\mathscr{G}^2}$$

where $f_x = \sqrt{x(1-x)}$ and \mathscr{A}_2 is the normalization factor.

Fig. 4 confirms that the QSI is valid in this case, however, it takes more time to reach the equality with the varying noise parameter.

2. Classical noise

We now consider the case where the control qubit is prepared in the Fourier basis, i.e., $\omega_c = p|+\rangle_c\langle+|+(1-p)|-\rangle_c\langle-|$, and the measurement on the control qubit is performed in the POVM set, $\{\mathcal{M}_{q_1,q_2}, \mathbb{I} - \mathcal{M}_{q_1,q_2}\}$, where $\mathcal{M}_{q_1,q_2} = q_1|+\rangle_c\langle+|+q_2|-\rangle_c\langle-|$. The final state of the target system after the measurement is performed on the above basis would be given by:

$$\Phi_{t}^{S}(\boldsymbol{\rho}) = \frac{1}{\mathscr{A}_{3}} \operatorname{Tr}_{c} \left(\mathscr{M}_{q_{1},q_{2}} S(\boldsymbol{\rho} \otimes \boldsymbol{\omega}_{c}) \right) = \\ \left(\begin{array}{c} A_{pq_{1}q_{2}}(t) \boldsymbol{\rho}_{11}(0) + B_{pq_{1}q_{2}}(t) \boldsymbol{\rho}_{22}(0) & C_{pq_{1}q_{2}}(t) \boldsymbol{\rho}_{12}(0) \\ C_{pq_{1}q_{2}}(t) \boldsymbol{\rho}_{21} & B_{pq_{1}q_{2}}(t) \boldsymbol{\rho}_{11}(0) + A_{pq_{1}q_{2}}(t) \boldsymbol{\rho}_{22}(0) \end{array} \right)$$

$$(29)$$

with
$$A_{pq_1q_2}(t) = (1 + C_{pq_1q_2}(t))/2$$
, $B_{pq_1q_2}(t) = (1 - C_{pq_1q_2}(t))/2$, and

$$C_{pq_1q_2}(t) = \frac{(-1+10p+\mathscr{G}^2(-1+2p)+\mathscr{G}(2-4p))q_1 - (-9+10p+\mathscr{G}^2(-1+2p)+\mathscr{G}(2-4p))q_2}{(3-6p+\mathscr{G}^2(3+2p)+6\mathscr{G}(-1+2p))q_1 - (3-6p+\mathscr{G}^2(-5+2p)+\mathscr{G}(-1+2p))q_2},$$

FIG. 4. Here we depict the QSI for a noisy QS described in Section IV C 1. The difference between the left and right-hand sides of Eq. (15) for $\rho = |1\rangle\langle 1|$ and $\gamma = 1$. For $\{p, q\} = (a) \{1/2, 1/2\}$, (b) $\{2/5, 1\}$, and (c) $\{4/5, 9/10\}$

where \mathscr{A}_3 is the normalization factor.

Fig. 5 confirms the validity of QSI for this noisy QS, though, similar to the case of quantum noise, it takes more time to reach the equilibrium with the addition of noise.

V. LINDBLAD DYNAMICS OF THE SWITCHED CHANNEL

We are now in a position to derive the canonical Lindblad-type master equation for the dynamical map generated under the action of the QS. It is important to note that after the switching action, when the control bit is finally measured, we consider the dynamics of only one outcome ('+') even though both outcomes ('+','-') are possible. Therefore, it may seem that after normalizing,

FIG. 5. Here we depict the uncertainty deviation for the "classical noise case" for $\rho = |1\rangle\langle 1|$, with $\{p, q_1, q_2\} =$ (a) $\{1, 1, 0\}$, (b) $\{1/2, 1/2, 1/2\}$, and (c) $\{4/5, 1/10, 9/10\}$

the operation may not be linear anymore, and hence deriving the Lindblad equation is not possible. However, in our case, the trace of the final state density matrix [Eq. (27)] is independent of the initial state (since A(t) + B(t) = 1) and thus, the linearity is left intact. In particular, we prove that for any generalized Pauli channel represented by Eq. (6), the final map after post-selection is independent of the initial state.

■ **Statement 2:** For any generalized Pauli channel, the final map obtained after post-selection and the switch action presented in Eq. (27) is linear.

Proof. Using the properties of the Weyl operators, we can show that

$$\operatorname{Tr}\left[\rho\sum_{k,l,r,s}\widetilde{W}_{klrs}^{\dagger}\widetilde{W}_{klrs}\right] = \operatorname{Tr}\left[\rho\sum_{k,l,r,s}\frac{p_{kl}p_{rs}}{2}(1+\omega^{ks-rl})\mathbb{I}\right]$$
$$=\sum_{k,l,r,s}\frac{p_{kl}p_{rs}}{2}(1+\omega^{ks-rl}).$$
(30)

This shows that the trace is independent of the input density matrix and hence the linearity is preserved. $\hfill\square$

In Appendix D, we briefly sketch the method to obtain the Lindblad operator for a dynamical map. Applying it on Eq. (27), we get the corresponding Lindblad-type master equation of the form

$$\frac{d}{dt}\boldsymbol{\rho}(t) = \Gamma_{\mathcal{S}}(t) \sum_{i=1}^{3} \left(\boldsymbol{\sigma}_{i} \cdot \boldsymbol{\rho}(t) \cdot \boldsymbol{\sigma}_{i} - \boldsymbol{\rho}(t) \right),$$
(31)

with

$$\Gamma_{S}(t) = 8\gamma \times \frac{\cosh(4\gamma t) - 2\sinh(4\gamma t) + 3}{5\cosh(4\gamma t) - 4\sinh(4\gamma t) - 1} \\ \times \frac{1}{4\sinh(4\gamma t) + \cosh(4\gamma t) + 3} \\ = 16\gamma \times \frac{(-\mathcal{G})(\mathcal{G}^{2} - 6\mathcal{G} - 3)}{(\mathcal{G}^{2} - 2\mathcal{G} + 9)(5\mathcal{G}^{2} + 6\mathcal{G} - 3)}$$
(32)

The above coefficient becomes negative with time as shown in Fig. 6. This implies the QS has converted the initial Markovian operation (i.e., the completely depolarizing channel) into a non-Markovian one.

A. Emergent non-Markovianity from the quantum switch

We further explore various aspects of non-Markovianity [30–46] emerging from the QS dynamics. Quantum non-Markovianity can be measured in several ways. One such measure is based on the divisibility of a dynamical map which was first proposed by Rivas, Huelga and Plenio

(RHP) [32].

RHP measure: The dynamical map $\Phi_{\Delta t} \equiv \Phi(t + \Delta t, t)$ is CP if and only if $(\mathbb{I} \otimes \Phi_{\Delta t}) |\psi\rangle \langle \psi| \geq 0$ for all Δt [32], where \mathbb{I} stands for the identity map. Utilizing the trace-preserving condition, we can use the identity $||(\mathbb{I} \otimes \Phi_{\Delta t}) |\psi\rangle \langle \psi|||_1 = 1$ if and only if $\Phi_{\Delta t}$ is CP; otherwise $||(\mathbb{I} \otimes \Phi_{\Delta t}) |\psi\rangle \langle \psi|||_1 > 1$. Using this property, the RHP measure is defined as

$$g(t) = \lim_{\Delta t \to 0} \frac{\left| \left| \mathbb{I} \otimes \Phi_{\Delta t} \left| \psi \right\rangle \left\langle \psi \right| \right| \right|_{1} - 1}{\Delta t}, \quad (33)$$

where $\Phi_{\Delta t} = \mathbb{I} + \Delta t \mathscr{L}_t$. The integral $\int_0^{\infty} g(t) dt$ can be considered as a measure of non-Markovianity. For the switch operation, it is straightforward to calculate that $g(t) = 6|\Gamma_S(t)|$. Therefore, from the perspective of the divisibility of dynamical maps, we can measure the QS-induced non-Markovianity with

$$N_{S} = \int_{T_{-}}^{\infty} g(t)dt = \int_{T_{-}}^{\infty} 6|\Gamma_{S}(t)|dt,$$
 (34)

or the normalized measure,

$$\mathcal{N}_S = \frac{N_S}{1 + N_S}.$$
(35)

In Fig. 6(a), the RHP measure of non-Markovianity is depicted for different values of γ . It clearly shows the time dependence of the emergent non-Markovianity due to the QS.

BLP measure: Another well-known measure of non-Markovianity was proposed by Breuer, Laine, and Piilo (BLP) [31, 67]. They characterized non-Markovian dynamics by the information backflow from the environment to the system. Usually, the distinguishability between two states decreases under Markovian dynamics as information moves from the system to the environment. Thus, an increase in the distinguishability of a pair of evolving states indicates information backflow under the dynamics. According to the BLP measure, a dynamics is non-Markovian if there exists a pair of states whose distinguishability increases for some time *t*. The time derivative of the distance between two states ρ and τ evolving under the QS is given as

$$\mathscr{B} \equiv \frac{d}{dt} D(\Phi_t^S(\rho), \tau).$$
(36)

The above expression implies that the second state, τ is actually the fixed point of the dynamics. This choice reduces the complexity of calculation while retaining the physical meaning of the measure with its generality. The BLP measure of non-Markovianity is calculated by integrating \mathscr{B} over the time where $\mathscr{B} > 0$ and then optimizing over all

possible input states ρ ,

$$N_{\text{inf}} = \max_{\rho} \int_{T_{-}}^{\infty} \mathscr{B} dt$$

=
$$\max_{\rho} \left[D(\Phi_{\infty}^{S}(\rho), \tau) - D(\Phi_{T_{-}}^{S}(\rho), \tau) \right].$$
(37)

For the qubit-depolarizing dynamics, this quantity can be readily derived as follows. Let us consider an arbitrary initial state $\rho = \frac{1}{2} (\mathbb{I} + \vec{n} \cdot \vec{\sigma})$, where $\vec{n} = \{n_x, n_y, n_z\}$ with $n_x^2 + n_y^2 + n_z^2 \leq 1$ and the other symbols have there usual meanings. For the qubit depolarizing channel, the fixed point is $\tau = \mathbb{I}/2$. For the switch dynamics given in Eq. (27), the dynamic trace distance between $\Phi_t^S(\rho)$ and $\mathbb{I}/2$ can be calculated as

$$D(\Phi_{\infty}^{S}(\rho), \tau) - D(\Phi_{T_{-}}^{S}(\rho), \tau)$$

= { $C(\infty) - C(T_{-})$ } $\sqrt{n_{x}^{2} + n_{y}^{2} + n_{z}^{2}}$, (38)

where C(t) is given in Eq. (27). Since the (state-dependent) quantity under the square root can be at most 1, we get

$$N_{\rm inf} = C(\infty) - C(T_{-}).$$
 (39)

Similarly, we can calculate the switch-induced memory as

$$\mathscr{Q}_{S}(\infty) = D(\Phi_{\infty}^{S}(\rho), \tau) = C(\infty).$$
(40)

This establishes the direct connection between the emergent non-Marvonianity and the QSM. Evidently, the switchinduced information backflow is just the QSM with a negative offset of $C(T_{-})$, a constant. Moreover, we can consider the normalized BLP measure,

$$\mathcal{N}_{\rm BLP} = \frac{N_{\rm inf}}{1 + N_{\rm inf}},\tag{41}$$

to get

$$\mathscr{Q}_{\mathcal{S}}(\infty) = \frac{\mathscr{N}_{\mathsf{BLP}}}{1 - \mathscr{N}_{\mathsf{BLP}}} + C(T_{-}).$$
(42)

We can also consider a normalized QSM measure:

$$\mathcal{N}_{\mathcal{S}}^{\infty} = \frac{\mathscr{Q}_{\mathcal{S}}(\infty)}{1 + \mathscr{Q}_{\mathcal{S}}(\infty)},\tag{43}$$

which gives us the following relation:

$$\mathcal{N}_{S}^{\infty} = \frac{\mathcal{N}_{\text{BLP}} + C(T_{-})(1 - \mathcal{N}_{\text{BLP}})}{1 + C(T_{-})(1 - \mathcal{N}_{\text{BLP}})}.$$
 (44)

In highly non-Markovian cases where $\mathcal{N}_{BLP} \to 1$, it gives $\mathcal{N}_{S}^{\infty} \to \mathcal{N}_{BLP}$.

In Fig. 6(b), the BLP measure of non-Markovianity is shown for different values of γ , which shows the evolution of information backflow of the emergent non-Markovian dynamics with time. From Fig. 6, it is evident that, at a certain characteristic time, there is a clear transition from Markovian to non-Markovian behaviour for the concerned dynamics. Below, we analyse this particular issue.

FIG. 6. Here, we represent the evolution of RHP and BLP measure for the given qubit dynamics, for three different values of γ as mentioned in the plot. It depicts the emergent non-Markovianity due to the action of QS. It also shows that the information backflow (plot (b)) emerges at the same time when divisibility of the channel breaks down (plot (a))

B. Characteristic time

Let T_{-} be the characteristic time— the earliest time when information backflow starts. This is the time when the Lindblad coefficient in Fig. 6 turns negative; below, we show this explicitly. Let us consider two arbitrary states,

$$\chi_i(t) = \frac{1}{2} (\mathbb{I} + \vec{\sigma} \cdot \vec{n}_i(t))$$
(45)

with i = 1, 2, and $\vec{n}_i(t) = \{n_i^1(t), n_i^2(t), n_i^3(t)\}$. The trace distance between these two states can be written as

$$D(\chi_1(t),\chi_2(t)) = \sqrt{(a_1(t))^2 + (a_2(t))^2 + (a_3(t))^2},$$
 (46)

where $a_k(t) = n_1^k(t) - n_2^k(t)$. Since, at $t = T_-$, the trace distance attains an extremum value, its time derivative vanishes, i.e.,

$$\frac{d}{dt}D(\chi_1(T_-),\chi_2(T_-)) = 0.$$
(47)

After simplification, this condition reduces to

$$\lim_{\varepsilon \to 0} \sum_{i=1}^{3} \left[(a_i(T_- + \varepsilon))^2 - (a_i(T_-))^2 \right] = 0.$$
 (48)

Expanding, we get $a_i(T_- + \varepsilon) = a_i(T_-)(1 + \varepsilon \Gamma_s(T_-))$. This implies, $((a_1(T_-))^2 + (a_2(T_-))^2 + (a_3(T_-))^2)\Gamma_s(T_-) = 0$. Clearly, the time derivative of the trace distance becomes zero and then positive, exactly when $\Gamma_s(t)$ becomes zero and then negative. Therefore, the characteristic time $T_$ can be evaluated from the equation $\Gamma_s(T_-) = 0$. We thus get

$$\cosh(4\gamma T_{-}) - 2\sinh(4\gamma T_{-}) + 3 = 0$$

or, $\mathscr{G}_{-}^{2} - 6\mathscr{G}_{-} - 3 = 0$, with $\mathscr{G}_{-} = e^{4\gamma T_{-}}$. (49)

Solving this, we obtain the expression of characteristic time as,

$$T_{-} = \frac{1}{4\gamma} \ln\left(2\sqrt{3} + 3\right).$$
 (50)

In the literature of quantum non-Markovianity, the system-environment correlation is considered one of the primary reasons behind the generation of non-Markovian dynamics. In the case of the QS, the control qubit can be interpreted as a part of the environment and the QSM can be understood as the emergent non-Markovianity. Here it is important to remember that CP-divisible operations are not convex. Therefore for two such operations, Φ_1 and Φ_2 , the operation $p\Phi_1 \circ \Phi_2 + (1-p)\Phi_2 \circ \Phi_1$ may not be CP divisible. One may question the usefulness of the QS for the emergence of non-Markovianity, as discussed previously. Indeed, if one uses two different CP-divisible operations, the QS is not unique in generating non-Markovian dynamics that can be called a "self-switching process". However, if one uses the same operations as $\Phi_1 = \Phi_2 = \Phi$, neither convex combination nor any series or parallel combinations of those operations can produce non-Markovian dynamics, except the OS.

Finally, we study the emergent non-Markovianity due to the QS for a general qubit Pauli channel given in Eq. (23) with constant but different Lindblad coefficients, in terms of the normalized RHP measure \mathcal{N}_S . The result is shown in Fig. 7 for multiple Lindblad coefficients. The figure shows that by manipulating the coefficients, we can produce highly non-Markovian dynamics, starting from a purely Markovian depolarizing evolution.

FIG. 7. In this plot, we show the emergent non-Markovianity in terms of \mathcal{N}_S for QS action over a general Pauli channel given in Eq. (23) with different Lindblad coefficients. In case (a) we consider $\gamma_3 = 0$ and vary γ_1 and γ_2 from 0 to 1. We see that for high values of them, the QS channel is highly non-Markovian. In case (b), we see similar features for $\gamma_2 = 0$.

VI. DISCUSSION

A series of recent works establish the advantages arizing from the superposition of alternative causal orders over the superposition of alternative trajectories. Although recent debates suggest that the advantages appearing due to the superposition of causal order can be achieved and even be surpassed by the superposition of direct pure process with definite order [72], proper characterization and adequate quantification of indefinite causal order are still not well understood. With this motivation, in this paper, we explore the dynamical behaviour of the QS and characterize the non-Markovian memory that emerges from it. We first investigate how the loss of information of a general quantum evolution changes when it is subjected to the QS and, on this backdrop, we propose a quantification of the switch-induced memory, QSM. We then derive an uncertainty relation between the information loss and the QSM, which captures the interplay between information storage capacity and the QSM. Furthermore, we show that after a sufficiently long period of time, as the dynamics approaches the steady state, the uncertainty inequality reduces to an equality, implying a complementarity between the longtime averaged loss of information and the QSM. We then consider an example of completely depolarizing dynamics for qubit and explore its behaviour under the action of QS. We make both the control qubit and the final measurement on the control qubit noisy and look at the amount of noise that a quantum switch can tolerate. Further, we derive the reduced operation of the switch action on the qubit both in terms of the Kraus representation and Lindblad evolution and verify the uncertainty relation in this particular case. We then attribute this effect of the QS for activating a completely depolarizing channel to the non-Markovian memory that emerges from the switch-induced memory. Comparing it with other standard measures of non-Markovianity, we show that the long-term memory of a QS is equivalent to the emergent non-Markovianity.

Our work is particularly relevant from several backdrops of quantum information theory. While investigating the dynamical behaviour of a quantum switch, we find that the quantum switch actually carries some non-Markovian memory. The emergence of such non-Markovian memory induced by the quantum switch is quite important for further developments of quantum technology and near-term quantum devices. Furthermore, this investigation also allows us to quantify the amount of memory a quantum switch can possess. In other words, our study opens up a new avenue for quantifying the amount of noise a quantum switch can tolerate. To the best of our knowledge, this is the first study for adequate quantification of the quantum switch, a well-established quantum resource for future quantum technologies.

Appendix A: Calculation of the time-averaged state of the dynamical map

As mentioned earlier, for a completely depolarizing channel, the dynamical map is given by the following equations:

$$\begin{split} \rho_{11}(t) &= \rho_{11}(0) \left(\frac{1 + e^{-2\xi_1(t)}}{2} \right) + \rho_{22}(0) \left(\frac{1 - e^{-2\xi_1(t)}}{2} \right) \\ \rho_{22}(t) &= 1 - \rho_{11}(t), \\ \rho_{12}(t) &= \rho_{12}(0) e^{-\xi_2(t)}, \end{split}$$

with

$$\xi_1(t) = \int_0^t [\gamma_1(s) + \gamma_2(s)] ds \quad \text{and}$$

$$\xi_2(t) = \int_0^t [\gamma_2(s) + \gamma_3(s)] ds.$$

Now the time-averaged state for the above dynamics is given by

$$\overline{\rho} = \lim_{T \to \infty} \frac{\int_0^T \Phi_t(\rho) dt}{\int_0^T dt} \\ = \lim_{T \to \infty} \frac{\int_0^T \left(\begin{array}{cc} \rho_{11}(t) & \rho_{12}(t) \\ \rho_{21}(t) & \rho_{22}(t) \end{array} \right) dt}{\int_0^T dt} = \left(\begin{array}{cc} \frac{1}{2} & 0 \\ 0 & \frac{1}{2} \end{array} \right) = \frac{\mathbb{I}}{2}$$

If τ is a fixed point of the dynamical map Φ , then

$$\mathscr{L}_t(\tau) = \sum_{i=0}^3 \gamma_i [\sigma_i \tau \sigma_i - \tau] = 0.$$

Solving the above equations, we get

$$\tau = \left(\begin{array}{cc} \frac{1}{2} & 0\\ 0 & \frac{1}{2} \end{array}\right) = \frac{\mathbb{I}}{2}.$$

This shows that the ergodicity condition is satisfied.

Appendix B: Kraus representation of the quantum switch

The evolution of the combined state of the target system and the control qubit under the switch is given by

$$S(\mathscr{E},\mathscr{E})(\boldsymbol{\rho}\otimes\boldsymbol{\omega}_{c})=\sum_{i,j}S_{ij}(\boldsymbol{\rho}\otimes\boldsymbol{\omega}_{c})S_{ij}^{\dagger}$$

The state of the target system after measuring the control qubit in the $\{|\pm\rangle_c \langle \pm|\}$ basis is given by $_c \langle +|S(\mathscr{E},\mathscr{E})(\rho \otimes |+\rangle_c \langle +|)|+\rangle_c$. This can also be written as

$$\sum_{i,j} M_{ij} \rho M_{ij}^{\dagger}$$

with

$$M_{ij} = \frac{K_i K_j + K_j K_i}{2}$$

and $\sum_{i,j} M_{ij}^{\dagger} M_{ij} \leq \mathbb{I}$. The equality holds if $[K_i, K_j] = 0$ or $[K_i, K_j^{\dagger}] = 0$ or both. Therefore, the switch action

$$\Phi_t^S(\rho) = \frac{\sum_{i,j} M_{ij} \rho M_{ij}^{\dagger}}{\operatorname{Tr} \left[\rho \sum_{i,j} M_{ij}^{\dagger} M_{ij} \right]}$$

Now, this operation is CPTP, but the linearity is only confirmed if $\text{Tr}\left[\rho \sum_{i,j} M_{ij}^{\dagger} M_{ij}\right]$ is independent of ρ . For our case it is independent of ρ , so linearity is confirmed.

Appendix C: Proof of Statements 1 and 2 for the control qubit in the superposition state and measurement with a parameter

Here we will prove **Statement 1** and **Statement 2** for a general switch operation which includes all the cases discussed in Sections III, IV, and V. A general quantum switch operation can be represented by

$$\Phi_{t}^{S}(\rho) = \frac{1}{\mathscr{P}} Tr_{c} \left[M_{\alpha} \left(\sum_{ij} W_{ij} \rho \otimes \omega_{c} W_{ij}^{\dagger} \right) \right]$$

with $\omega_c = \sum_{\kappa} q_{\kappa} |\psi_{\kappa}\rangle \langle \psi_{\kappa}|$ being a general qubit control state, $M_{\alpha} = A_{\alpha}^{\dagger} A_{\alpha}$ being a general Positive operator valued measure, \mathscr{P} being the normalization factor, $W_{ij} = K_i K_j \otimes |0\rangle \langle 0| + K_j K_i \otimes |1\rangle \langle 1|$ where K_i s are the Kraus operators for the original quantum operation and $Tr_c[$] representing partial trace over the control basis. For this setting, the reduced Kraus representation can be expressed as

$$\tilde{K}_{ij} = \chi_1 K_i K_j + \chi_2 K_j K_i,$$

with $\chi_1 = \sum_{l,\kappa} \sqrt{q_\kappa} \langle \psi_l | A_\alpha | 0 \rangle \langle 0 | \psi_\kappa \rangle$ and $\chi_2 = \sum_{l,\kappa} \sqrt{q_\kappa} \langle \psi_l | A_\alpha | 1 \rangle \langle 1 | \psi_\kappa \rangle$. Therefore the switch operation can be represented as

$$\Phi_t^S(
ho) = rac{1}{\mathscr{P}} \sum_{ij} ilde{K}_{ij}
ho ilde{K}_{ij}^\dagger,$$

with $\mathscr{P} = Tr\left[\sum_{ij} \tilde{K}_{ij} \rho \tilde{K}_{ij}^{\dagger}\right]$. Using this general representation for arbitrary dimensional depolarizing operations represented in Eq. (6) and following the same method, we can prove **Statement 1** and **Statement 2** for such general switch actions. It is to be noted that the dynamical maps constructed in Eqs. (27), (28), and (29) are all special cases of the general form discussed in this appendix.

Appendix D: Construction of the master equation

Let us now consider a dynamical map of the form

$$\boldsymbol{\rho}(t) = \boldsymbol{\Omega}[\boldsymbol{\rho}(0)]. \tag{D1}$$

Further, consider the equation of motion corresponding to the previous dynamical equation to be

$$\dot{\rho}(t) = \tilde{\Lambda}[\rho(t)]$$
 (D2)

where $\tilde{\Lambda}[.]$ is the generator of the dynamics. Now following Ref. [73, 74], we can find the master equation and generator of the dynamics.

Let $\{\mathscr{G}_i\}$ denotes the orthonormal basis set with the properties $\mathscr{G}_0 = \mathbb{I}/\sqrt{2}$, $\mathscr{G}_i^{\dagger} = \mathscr{G}_i$, \mathscr{G}_i are traceless except \mathscr{G}_0 and $\operatorname{Tr}[\mathscr{G}_i\mathscr{G}_i] = \delta_{ij}$. The map in Eq. (D1) can be represented as

$$\Omega[\rho(0)] = \sum_{m,n} \operatorname{Tr}[\mathscr{G}_m \Omega[\mathscr{G}_n]] \operatorname{Tr}[\mathscr{G}_n \rho(0)] \mathscr{G}_m = [F(t)r(0)] \mathscr{G}^T$$

where $F_{mn} = \text{Tr}[\mathscr{G}_m\Omega[\mathscr{G}_n]]$ and $r_n(s) = \text{Tr}[\mathscr{G}_n\rho(s)]$. Taking time-derivative of the above equation we shall get

$$\dot{\boldsymbol{\rho}}(t) = [\dot{F}(t)r(0)]\mathscr{G}^T.$$

Let us now consider a matrix *L* with elements $L_{mn} = \text{Tr}[\mathscr{G}_m \tilde{\Lambda}[\mathscr{G}_n]]$. We can therefore represent Eq. (D2) as

$$\dot{\boldsymbol{\rho}}(t) = \sum_{m,n} \operatorname{Tr}[\mathscr{G}_m] \tilde{\Lambda}[\mathscr{G}_n] \operatorname{Tr}[\mathscr{G}_n \boldsymbol{\rho}(t)] \mathscr{G}_m = [L(t)r(t)] \mathscr{G}^T.$$

Comparing the above two equations, we find

$$\dot{F}(t) = L(t)F(t) \implies L(t) = \dot{F}(t)F(t)^{-1}$$

- [8] Giulio Chiribella, Manik Banik, Some Sankar Bhattacharya,

One may note that L(t) can be obtained if $F(t)^{-1}$ exists and $F(0) = \mathbb{I}$. From this L(t) matrix, we can derive the corresponding master equation following the methods given in Refs. [73, 74]. It is to be noted that of the dynamical maps constructed in Eqs. (27), (28), and (29), all have the following form

$$\rho_{11}(t) = \left(\frac{1+\mathscr{C}(t)}{2}\right)\rho_{11}(0) + \left(\frac{1-\mathscr{C}(t)}{2}\right)\rho_{22}(0),$$

$$\rho_{22}(t) = \left(\frac{1-\mathscr{C}(t)}{2}\right)\rho_{11}(0) + \left(\frac{1+\mathscr{C}(t)}{2}\right)\rho_{22}(0),$$

$$\rho_{12}(t) = \mathscr{C}(t)\rho_{12}(0), \quad \rho_{21}(t) = \rho_{12}^{*}(t),$$
(D3)

where $\mathscr{C}(t)$ is a real function of time. For these evolutions, the L(t) matrices will be of the form

$$L(t) = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & \frac{d}{dt} \ln \mathscr{C}(t) & 0 & 0 \\ 0 & 0 & \frac{d}{dt} \ln \mathscr{C}(t) & 0 \\ 0 & 0 & 0 & \frac{d}{dt} \ln \mathscr{C}(t) \end{pmatrix}.$$
 (D4)

The corresponding master equation will be of the form

$$\frac{d}{dt}\rho(t) = \Gamma_{\mathscr{C}}(t)\sum_{i} \left[\sigma_{i}\rho(t)\sigma_{i} - \rho(t)\right], \qquad (D5)$$

with

$$\Gamma_{\mathscr{C}}(t) = -\frac{1}{4}\frac{d}{dt}\ln \mathscr{C}(t).$$
