Abstract—In this paper, we analyze the impact of data freshness on remote inference systems, where a pre-trained neural network infers a time-varying target (e.g., the locations of vehicles and pedestrians) based on features (e.g., video frames) observed at a sensing node (e.g., a camera). One might expect that the performance of a remote inference system degrades monotonically as the feature becomes stale. Using an information-theoretic analysis, we show that this is true if the feature and target data sequence can be closely approximated as a Markov chain, whereas it is not true if the data sequence is far from Markovian. Hence, the inference error is a function of Age of Information (AoI), where the function could be non-monotonic. To minimize the inference error in real-time, we propose a new “selection-from-buffer” model for sending the features, which is more general than the “generate-at-will” model used in earlier studies. In addition, we design low-complexity scheduling policies to improve inference performance. For single-source, single-channel systems, we provide an optimal scheduling policy. In multi-source, multi-channel systems, the scheduling problem becomes a multi-action restless multi-armed bandit problem. For this setting, we design a new scheduling policy by integrating Whittle index-based source selection and duality-based feature selection-from-buffer algorithms. This new scheduling policy is proven to be asymptotically optimal. These scheduling results hold for minimizing general AoI functions (monotonic or non-monotonic). Data-driven evaluations demonstrate the significant advantages of our proposed scheduling policies.

Index Terms—Age of Information, remote inference, goal-oriented communications, scheduling, buffer management.

I. INTRODUCTION

Next-generation communications (Next-G), such as 6G, are expected to enable emerging networked intelligent systems, including autonomous driving, factory automation, digital twins, UAV navigation, and extended reality. These systems rely on timely inference, where a pre-trained neural network infers time-varying targets (e.g., vehicle and pedestrian locations) using features (e.g., video frames) transmitted from sensing nodes (e.g., cameras). Due to communication delay and transmission errors, the features delivered to the neural network may not be fresh. Traditionally, information freshness has not been a major concern in inference systems. However, in time-sensitive applications, it is critical to understand how information freshness impacts inference performance.

This paper was presented in part at ACM MobiHoc, 2022 [1]. M.K.C. Shisher and Y. Sun are with the Department of Electrical and Computer Engineering, Auburn University, Auburn, AL, 36849 (e-mail: mzs0153@auburn.edu, yzs0078@auburn.edu). I.-H. Hou is with the Department of Electrical and Computer Engineering, Texas A&M University, College Station, TX 77843 USA (e-mail: ihou@tamu.edu). The work of M.K.C. Shisher and Y. Sun was supported in part by the NSF grant CNS-2239677 and the ARO grant W911NF-21-1-0244. The work of I.-H. Hou was supported in part by NSF under Award Number ECCS-2127721, in part by the U.S. Army Research Laboratory and the U.S. Army Research Office under Grant Number W911NF-22-1-0151, and in part by Office of Naval Research under Contract N00014-21-1-2385.

The concept of Age of Information (AoI), introduced in [2], [3], measures the freshness of information at the receiver. Consider packets sent from a source to a receiver. If $U(t)$ is the generation time of the freshest received packet by time t , then the AoI $\Delta(t)$ is defined as the time difference between the current time t and the generation time $U(t)$ of the freshest received packet, expressed as

$$\Delta(t) = t - U(t). \quad (1)$$

A smaller AoI indicates more recent information at the receiver. While existing AoI research extensively analyzes and optimizes linear and nonlinear functions of AoI [4]–[16], there is a lack of comprehensive understanding on how to assess the value of fresh information in real-time systems. This gap motivates us to seek a more suitable analysis for evaluating the significance of fresh information for systems using it.

Previous studies [4]–[16] assumed system performance degrades monotonically with stale information (i.e., fresher data is always better). However, our remote inference experiments (see Sec. II-C) demonstrate that this assumption holds in some scenarios (e.g., video prediction), but not in others (e.g., temperature prediction or reaction prediction). For example, in predicting next hour temperature, temperature recorded at 24 hours ago is more relevant than temperature recorded at 12 hours ago due to daily weather patterns. Moreover, consider an example of reaction prediction: If a vehicle initiates braking, nearby vehicles don’t react instantly due to the response delay of the drivers or the braking systems. Therefore, slightly outdated actions can be more relevant for predicting reactions than the most current action. These observations highlight that fresher data is not always better. To accurately assess the value of fresh information, we need a robust analytical framework.

In this paper, we first present a new information-theoretic analysis to reveal when fresher data is always better and when it is not. In the second part of this paper, we focus on optimal communication system design for remote inference. Most existing studies in AoI literature [4]–[16] have focused on designing transmission scheduling strategies to minimize monotonic functions of AoI. However, the design of efficient scheduling policies for optimizing general, potentially non-monotonic functions of AoI remains unexplored. To that end, we design the first transmission scheduling policies to minimize general functions of AoI, regardless of whether the functions are monotonic or non-monotonic. The contributions of this paper are summarized as follows:

- We conduct five experiments to examine the impact of data freshness on remote inference. These experiments include (i) video prediction, (ii) robot state prediction in a leader-follower robotic system, (iii) actuator state

prediction under mechanical response delay, (iv) temperature prediction, and (v) wireless channel state information (CSI) prediction. One might assume that the inference error degrades monotonically as the data becomes stale. Our experimental results show that this assumption is not always true. In some scenarios, even the fresh data with $\Delta(t) = 0$ may generate a larger inference error than stale data with $\Delta(t) > 0$ (see Figs 2-3).

- We develop two theoretical methods to interpret these counter-intuitive experimental results. First, by a local information geometric analysis, we show that the assumption “fresh data is better than stale data” is true when the time-sequence data used for remote inference can be closely approximated as a Markov chain; but it is not true when the data sequence is far from Markovian (Theorems 1-3). Hence, the inference error is a function of the AoI, whereas the function is not necessarily monotonic. This analysis provides an information-theoretic interpretation of information freshness. Second, we construct two analytical models to analyze and explain when fresh data is better than stale data and when it is not (see Sec. III-D).
- In the second part of the paper, we design transmission scheduling policies for minimizing the inference error. Because fresher data is not always better, we propose a new medium access model called the “selection-from-buffer” model, where B most recent features are stored in the source’s buffer and the source can choose to send any of the B most recent features. This model is more general than the “generate-at-will” model used in earlier studies, e.g., [4]–[9], [12]. If the inference error is a non-decreasing function of the AoI, the “selection-from-buffer” model achieves the same performance as the “generate-at-will” model; if the AoI function is non-monotonic, the “selection-from-buffer” model can potentially achieve better performance.
- For single-source and single-channel systems, an optimal scheduling policy is devised to determine (i) when to submit features to the channel and (ii) which feature in the buffer to submit. This scheduling policy is capable of minimizing general functions of the AoI, regardless of whether the function is monotonic or not. By leveraging a new index function $\gamma(\Delta(t))$, the optimal scheduling policy can be expressed as an *index-based threshold policy*, where a new packet is sent out whenever $\gamma(\Delta(t))$ exceeds a pre-determined threshold (Theorems 4-5). The threshold can be computed by using low complexity algorithms, e.g., bisection search. We note that the function $\gamma(\cdot)$ is *not necessarily monotonic* and hence its inverse function *may not exist*. Consequently, this index-based threshold policy cannot be equivalently expressed as an AoI-based threshold policy, i.e., a new packet is sent out whenever the AoI $\Delta(t)$ exceeds a pre-determined threshold. This is a key difference from prior studies on minimizing non-decreasing AoI functions [4]–[16], where the optimal scheduling policy is an AoI-based threshold policy.
- In multi-source and multi-channel systems, the scheduling problem is a restless multi-armed bandit (RMAB) problem with multiple actions. We propose a multi-

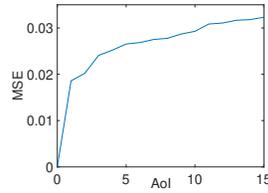

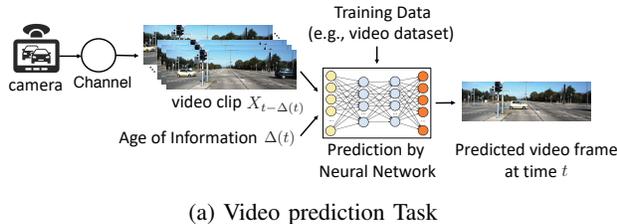

source, multi-action scheduling policy that uses a Whittle index algorithm to determine which sources to schedule and employs a duality-based selection-from-buffer algorithm to decide which features to schedule from the buffers of these sources. By utilizing linear programming (LP)-based priority conditions [17], [18], we establish the asymptotic optimality of this scheduling policy as the numbers of sources and channels tend to infinity, maintaining a constant ratio (see Theorem 11).

- The above results hold (i) for minimizing general AoI functions (monotonic or non-monotonic) and (ii) for random delay channels. Data-driven evaluations show that the optimal scheduler achieves up to 3 times smaller inference error compared to “generate-at-will” with optimal scheduling strategy and 8 times smaller inference error compared to periodic feature updating (see Fig. 9). Numerical results further validate the asymptotic optimality of the proposed scheduling policy (see Figs. 11-12).
- When the training and inference data have the same probabilistic distribution, remote inference reduces to signal-agnostic remote estimation. Hence, the results of the present work above also apply to signal-agnostic remote estimation.

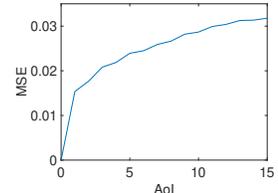

A. Related Works

The concept of Age of Information (AoI) has attracted significant research interest; see, e.g., [3]–[16], [20]–[27] and a recent survey [28]. Initially, research efforts were centered on analyzing and optimizing average AoI and peak AoI in communication networks [3]–[5], [13], [20]. Recent research endeavors on AoI have shifted towards optimizing the performance of real-time applications, such as remote estimation, remote inference, and control systems, by leveraging AoI as a tool. In [7], [8], [21], [23], information-theoretic metrics such as Shannon’s mutual information (or Shannon’s conditional entropy) has been used to quantify the amount of information carried by the received data about the current source value (or the amount of uncertainty regarding the current source value) as the data ages. In addition, a Shannon’s conditional entropy term $H_{\text{Shannon}}(Y_t|X_{t-\Delta(t)} = x, \Delta(t) = \delta)$ was used in [22] to quantify information uncertainty given the most recent observation $X_{t-\Delta(t)} = x$ and AoI $\Delta(t) = \delta$. The information-theoretic metrics in these prior studies [7], [8], [21]–[23] cannot be directly used to evaluate system performance. To bridge the gap, in the present paper, we use an L -conditional entropy $H_L(Y_t|X_{t-\Delta(t)}, \Delta(t))$, to approximate and analyze the inference error in remote inference, as well as the estimation error in remote estimation. For example, when the loss function $L(y, \hat{y})$ is chosen as a quadratic function $\|y - \hat{y}\|_2^2$, the L -conditional entropy $H_L(Y_t|X_{t-\Delta(t)}, \Delta(t)) = \mathbb{E}[(Y_t - \mathbb{E}[Y_t|X_{t-\Delta(t)}, \Delta(t)])^2]$ is exactly the minimum mean squared estimation error in signal-agnostic remote estimation. This approach takes a significant step to bridge the gap between AoI metrics and real-world applications, by directly mapping the AoI to the application performance metrics.

In the earlier AoI studies [4]–[16], it was usually assumed that the observed data sequence is Markovian and the

(b) Training Error vs. AoI

(c) Inference Error vs. AoI

Fig. 1: Performance of video prediction experiment. The experimental results in (b) and (c) are regenerated from [19]. The training and inference errors are non-decreasing functions of the AoI.

performance degradation caused by information aging was modeled as a monotonic AoI function. Hence, the earlier studies [4]–[9], [12] adopted “generate-at-will” status updating model, where the transmitter can only select the most recently generated signal. However, practical data sequence may not be Markovian [7]. In the present paper, we propose a new local geometric approach to analyze both Markovian and non-Markovian time-series data. For non-Markovian time-series data, fresh data is not always better. To that end, we propose a new status updating model called the “selection-from-buffer” model, where the transmitter has the option to send any of the B most recent features stored in the source buffer.

The optimization of linear and non-linear functions of AoI for multi-source scheduling is a restless multi-armed bandit (RMAB) problem. The multi-source problems in previous AoI studies [10], [13]–[16], [24] are RMABs with binary actions and focused on monotonic AoI functions, where Whittle index policy [29] is used to solve the problem. Our multi-source problem is an RMAB with multiple actions. Because of the multiple-action setup, the Whittle index alone can not be utilized to solve our problem. Consequently, we design a new asymptotically optimal policy for multi-action RMAB with general AoI functions (monotonic or non-monotonic).

This paper is also related to the field of signal-agnostic remote estimation. The prior studies [7], [9], [11], [24], [25], [30], [31] in signal-agnostic remote estimation focused on Gaussian and Markovian processes. The results presented in the current paper are applicable to more general processes.

II. INFORMATION FRESHNESS IN REMOTE INFERENCE: MODEL AND PERFORMANCE

A. Remote Inference Model

Consider the remote inference system illustrated in Fig. 1. In this system, a time-varying target $Y_t \in \mathcal{Y}$ (e.g., the position of the car in front) is predicted at time t , using a feature $X_{t-\Delta(t)} \in \mathcal{X}$ (e.g., a video clip) that was generated $\Delta(t)$ seconds ago at a sensor (e.g., a camera). The time difference $\Delta(t)$ between $X_{t-\Delta(t)}$ and Y_t is the AoI defined in (1). Each feature $X_t = (V_t, V_{t-1}, \dots, V_{t-u+1})$ is a time series of length u , extracted from the sensor’s output signal V_t . For example, if V_t is the video frame at time t , then X_t represents a video clip consisting of u consecutive video frames.

We focus on a class of popular supervised learning algorithms known as *Empirical Risk Minimization (ERM)* [32]. In freshness-aware ERM supervised learning algorithms,

a neural network is trained to generate an action $a = \phi(X_{t-\Delta(t)}, \Delta(t)) \in \mathcal{A}$, where $\phi: \mathcal{X} \times \mathbb{Z}^+ \mapsto \mathcal{A}$ is a function that maps a feature $X_{t-\Delta(t)} \in \mathcal{X}$ and its AoI $\Delta(t) \in \mathbb{Z}^+$ to an action $a \in \mathcal{A}$. The performance of learning is evaluated using a loss function $L: \mathcal{Y} \times \mathcal{A} \mapsto \mathbb{R}$, where $L(y, a)$ represents the loss incurred if action a is selected when $Y_t = y$. It is assumed that both \mathcal{Y} and \mathcal{X} are discrete and finite sets.

The loss function L is determined by the *goal* of the remote inference system. For example, in neural network-based minimum mean-squared estimation, the loss function is $L_2(\mathbf{y}, \hat{\mathbf{y}}) = \|\mathbf{y} - \hat{\mathbf{y}}\|_2^2$, where the action $a = \hat{\mathbf{y}}$ is an estimate of the target $Y_t = \mathbf{y}$ and $\|\mathbf{y}\|_2^2$ is the Euclidean norm of the vector \mathbf{y} . In softmax regression (i.e., neural network-based maximum likelihood classification), the action $a = Q_Y$ is a distribution of Y_t and the loss function $L_{\log}(y, Q_Y) = -\log Q_Y(y)$ is the negative log-likelihood of the target value $Y_t = y$.

B. Offline Training and Online Inference

A supervised learning algorithm consists of two phases: *offline training* and *online inference*. In the offline training phase, a neural network based predictor is trained using one of the following two approaches.

In the first approach, multiple neural networks are trained independently, using distinct training datasets with different AoI values. The neural network associated with an AoI value δ is trained by solving the following ERM problem:

$$\text{err}_{\text{training},1}(\delta) = \min_{\phi \in \Lambda} \mathbb{E}_{Y, X \sim P_{\tilde{Y}_0, \tilde{X}_{-\delta}}} [L(Y, \phi(X, \delta))], \quad (2)$$

where $P_{\tilde{Y}_0, \tilde{X}_{-\delta}}$ is the empirical distribution of the label \tilde{Y}_0 and the feature $\tilde{X}_{-\delta}$ in the training dataset, the AoI value δ is the time difference between \tilde{Y}_0 and $\tilde{X}_{-\delta}$, and Λ is the set of functions that can be constructed by the neural network.

In the second approach, a single neural network is trained using a larger dataset that encompasses a variety of AoI values. The ERM training problem for this approach is formulated as

$$\text{err}_{\text{training},2} = \min_{\phi \in \Lambda} \mathbb{E}_{Y, X, \Theta \sim P_{\tilde{Y}_0, \tilde{X}_{-\Theta}, \Theta}} [L(Y, \phi(X, \Theta))], \quad (3)$$

where $P_{\tilde{Y}_0, \tilde{X}_{-\Theta}, \Theta}$ is the empirical distribution of the label \tilde{Y}_0 , the feature $\tilde{X}_{-\Theta}$, and the AoI Θ within the training dataset, and the AoI Θ is the time difference between \tilde{Y}_0 and $\tilde{X}_{-\Theta}$.

In the online inference phase, the pre-trained neural predictor is used to predict the target Y_t in real-time. We assume that the process $\{(Y_t, X_t), t = 0, 1, 2, \dots\}$ is stationary and the processes $\{(Y_t, X_t), t = 0, 1, 2, \dots\}$ and $\{\Delta(t), t =$

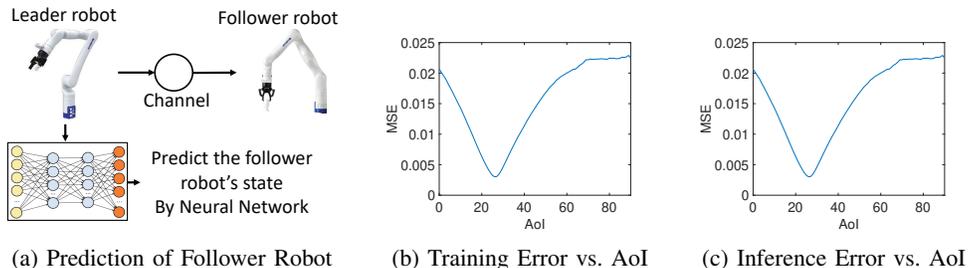

Fig. 2: Robot state prediction in a leader-follower robotic system. The leader robot uses a neural network to predict the follower robot’s state Y_t by using the leader robot’s state $X_{t-\delta}$ generated δ time slots ago ($u = 1$). The training and inference errors decrease in the $\text{AoI} \leq 25$ and increase when $\text{AoI} \geq 25$.

$0, 1, 2, \dots\}$ are independent. Under these assumptions, if $\Delta(t) = \delta$, the inference error at time t can be expressed as a function of the AoI value δ , i.e.,

$$\text{err}_{\text{inference}}(\delta) = \mathbb{E}_{Y_t, X \sim P_{Y_t, X_{t-\delta}}} [L(Y, \phi^*(X, \delta))], \quad (4)$$

where $P_{Y_t, X_{t-\delta}}$ is the distribution of the target Y_t and the feature $X_{t-\delta}$, and ϕ^* is the trained neural network. The proof of (4) is provided in Appendix E. In Sections V-VI, to minimize inference error, we will develop signal-agnostic transmission scheduling policies in which scheduling decisions are determined without using the knowledge of the signal value of the observed process. If the transmission schedule is signal-agnostic, then $\{(Y_t, X_t), t = 0, 1, 2, \dots\}$ is independent of the AoI process $\{\Delta(t), t = 0, 1, 2, \dots\}$.

C. Experimental Results on Information Freshness

We conduct five remote inference experiments to examine how the training error and the inference error vary as the AoI increases. These experiments include (i) video prediction, (ii) robot state prediction in a leader-follower robotic system, (iii) actuator state prediction under mechanical response delay, (iv) temperature prediction, and (v) wireless channel state information prediction. In these experiments, we consider the quadratic loss function $L(\mathbf{y}, \hat{\mathbf{y}}) = \|\mathbf{y} - \hat{\mathbf{y}}\|_2^2$. Detailed settings of these experiments can be found in Appendix A. We present the experimental results of the first training method in Figs. 1-5. Related codes and datasets are accessible in our GitHub repository.¹ To illustrate the training error of the second training method as a function of the AoI δ , one can simply assess the training error using the training data samples with the AoI value δ . As the results of the two training methods are similar, the experimental results of the second training method are omitted.

Fig. 1 presents the training error and inference error of a video prediction experiment, where a video frame V_t at time t is predicted using a feature $X_{t-\delta} = (V_{t-\delta}, V_{t-\delta-1})$ that is composed of two consecutive video frames. One can observe from Fig. 1(b)-(c) that both the training error and the inference error increase as the AoI δ increases.

Fig. 2 plots the performance of robot state prediction in a leader-follower robotic system, where a leader robot uses a neural network to predict the follower robot’s state Y_t by

using the leader robot’s state $X_{t-\delta}$ generated δ time slots ago. As depicted in Fig. 2, the training and the inference errors decrease in AoI, when $\text{AoI} \leq 25$ and increase in AoI when $\text{AoI} \geq 25$. In this case, even a fresh feature with $\text{AoI}=0$ is not good for prediction.

The performance of actuator state prediction under mechanical response delay is depicted in Fig. 3. We consider the OpenAI CartPole-v1 task [33], where the objective is to control the force on a cart and prevent the pole attached to the cart from falling over. The pole angle ψ_t at time t is predicted based on a feature $X_{t-\delta} = (v_{t-\delta}, \dots, v_{t-\delta-u+1})$ that consists of a consecutive sequence of cart velocity with length u generated δ milliseconds (ms) ago. As shown in Fig. 3, both the training error and the inference error exhibit non-monotonic variations as the AoI δ increases.

In Fig. 4 and Fig. 5, we plot the results of temperature prediction and wireless channel state information (CSI) prediction experiments, respectively. In both experiments, we observe non-monotonic trends in training error and inference error with respect to AoI, particularly when the length of the feature sequence u is small.

In the AoI literature, it has been generally assumed that the performance of real-time systems degrades monotonically as the data becomes stale. However, Figs. 1-5 reveal that this assumption is true in some scenarios, and not true in some other scenarios. Furthermore, Figs. 2-3 show that even the fresh data with $\text{AoI} = 0$ may generate a larger inference error than stale data with $\text{AoI} > 0$. These counter-intuitive experimental results motivated us to seek theoretical interpretations of information freshness in subsequent sections.

III. AN INFORMATION-THEORETIC INTERPRETATION OF INFORMATION FRESHNESS IN REMOTE INFERENCE

In this section, we develop an information-theoretic approach to interpret information freshness in remote inference.

A. Information-theoretic Metrics for Training and Inference

Because the set of functions Λ constructed by the neural network is complicated, it is difficult to directly analyze the training and inference errors by using (2)-(4). To overcome this challenge, we introduce information-theoretic metrics for the training and inference errors.

¹<https://github.com/Kamran0153/Impact-of-Data-Freshness-in-Learning>

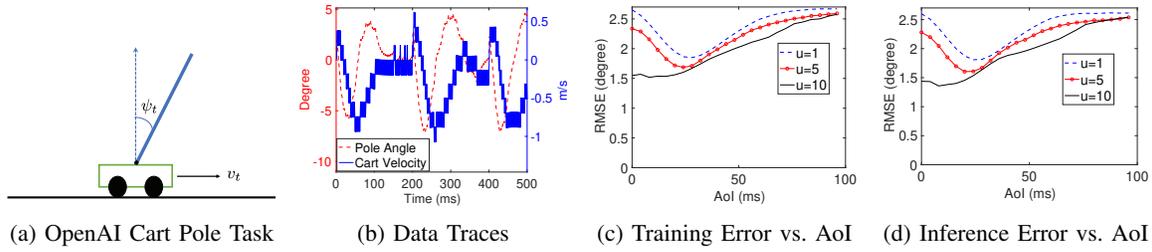

Fig. 3: Performance of actuator state prediction under mechanical response delay. In the OpenAI CartPole-v1 task [33], the pole angle ψ_t is predicted by using $X_{t-\delta} = (v_{t-\delta}, v_{t-\delta-1}, \dots, v_{t-\delta-u-1})$, where v_t is the cart velocity at time t . The training error and inference error are non-monotonic in the AoI.

1) *Training Error of the First Training Approach:* Let $\Phi = \{f : \mathcal{X} \times \mathbb{Z}^+ \mapsto \mathcal{A}\}$ be the set of all functions mapping from $\mathcal{X} \times \mathbb{Z}^+$ to \mathcal{A} . Any function ϕ constructed by the neural network belongs to Φ . Hence, $\Lambda \subseteq \Phi$. By relaxing the set Λ in (2) as Φ , we obtain the following lower bound of $\text{err}_{\text{training},1}(\delta)$:

$$H_L(\tilde{Y}_0 | \tilde{X}_{-\delta}) = \min_{\phi \in \Phi} \mathbb{E}_{Y, X \sim P_{\tilde{Y}_0, \tilde{X}_{-\delta}}} [L(Y, \phi(X, \delta))], \quad (5)$$

where $H_L(Y|X)$ is a generalized conditional entropy of Y given X , defined by [34]–[36]

$$H_L(Y|X) = \min_{\phi(x) \in \mathcal{A}, \forall x \in \mathcal{X}} \mathbb{E}_{X, Y \sim P_{X, Y}} [L(Y, \phi(X))]. \quad (6)$$

Compared to $\text{err}_{\text{training},1}(\delta)$, its information-theoretic lower bound $H_L(\tilde{Y}_0 | \tilde{X}_{-\delta})$ is mathematically more convenient to analyze. The gap between $\text{err}_{\text{training},1}(\delta)$ and $H_L(\tilde{Y}_0 | \tilde{X}_{-\delta})$ was studied recently in [37], where the gap is small if Λ and Φ are close to each other, e.g., when the neural network is sufficiently wide and deep [32].

For notational convenience, we refer to $H_L(Y|X)$ as an *L-conditional entropy*, because it is associated with a loss function L . The *L-entropy* of a random variable Y is defined as [34], [36]

$$H_L(Y) = \min_{a \in \mathcal{A}} \mathbb{E}_{Y \sim P_Y} [L(Y, a)]. \quad (7)$$

The *L-conditional entropy* of Y given $X = x$ is

$$H_L(Y|X = x) = \min_{a \in \mathcal{A}} \mathbb{E}_{Y \sim P_{Y|X=x}} [L(Y, a)]. \quad (8)$$

Using (6), one can get [34], [36]

$$\begin{aligned} H_L(Y|X) &= \sum_{x \in \mathcal{X}} P_X(x) \min_{a \in \mathcal{A}} \mathbb{E}_{Y \sim P_{Y|X=x}} [L(Y, a)] \\ &= \sum_{x \in \mathcal{X}} P_X(x) H_L(Y|X = x). \end{aligned} \quad (9)$$

2) *Training Error of the Second Training Approach:* A lower bound of the training error $\text{err}_{\text{training},2}$ in (3) is

$$H_L(\tilde{Y}_0 | \tilde{X}_{-\Theta}, \Theta) = \min_{\phi \in \Phi} \mathbb{E}_{Y, X, \Theta \sim P_{\tilde{Y}_0, \tilde{X}_{-\Theta}, \Theta}} [L(Y, \phi(X, \Theta))], \quad (10)$$

where $H_L(\tilde{Y}_0 | \tilde{X}_{-\Theta}, \Theta)$ is a L -conditional entropy of \tilde{Y}_0 given $(\tilde{X}_{-\Theta}, \Theta)$. Using (9), $H_L(\tilde{Y}_0 | \tilde{X}_{-\Theta}, \Theta)$ can be decomposed as

$$\begin{aligned} &H_L(\tilde{Y}_0 | \tilde{X}_{-\Theta}, \Theta) \\ &= \sum_{x \in \mathcal{X}, \delta \in \mathbb{Z}^+} P_{\tilde{X}_{-\Theta}, \Theta}(x, \delta) H_L(\tilde{Y}_0 | \tilde{X}_{-\delta} = x, \Theta = \delta). \end{aligned} \quad (11)$$

Similar to Sec. II-B, we assume that the label and feature $(\tilde{Y}_0, \tilde{X}_{-k})$ in the training dataset are independent of the training AoI Θ for every $k \geq 0$. Under this assumption, (11) can be simplified as (see Appendix F for its proof)

$$H_L(\tilde{Y}_0 | \tilde{X}_{-\Theta}, \Theta) = \sum_{\delta \in \mathbb{Z}^+} P_{\Theta}(\delta) H_L(\tilde{Y}_0 | \tilde{X}_{-\delta}), \quad (12)$$

which connects the information-theoretic lower bounds of $\text{err}_{\text{training},1}(\delta)$ and $\text{err}_{\text{training},2}(\delta)$.

3) *Inference Error:* Let a_{P_Y} be an optimal solution to (7), called a *Bayes action* [34]. If the neural predictor in (4) is replaced by the Bayes action $a_{P_{\tilde{Y}_0 | \tilde{X}_{-\delta} = x}}$, then, for both training methods, $\text{err}_{\text{inference}}(\delta)$ becomes the following L -conditional cross entropy

$$\begin{aligned} &H_L \left(P_{Y_t | X_{t-\delta}}; P_{\tilde{Y}_0 | \tilde{X}_{-\delta}} \middle| P_{X_{t-\delta}} \right) \\ &= \sum_{x \in \mathcal{X}} P_{X_{t-\delta}}(x) \mathbb{E}_{Y \sim P_{Y_t | X_{t-\delta} = x}} \left[L \left(Y, a_{P_{\tilde{Y}_0 | \tilde{X}_{-\delta} = x}} \right) \right], \end{aligned} \quad (13)$$

where the *L-cross entropy* is defined as

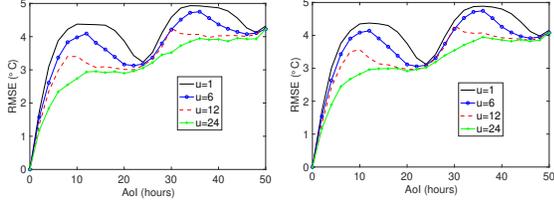

$$H_L(P_Y; P_{\tilde{Y}}) = \mathbb{E}_{Y \sim P_Y} [L(Y, a_{P_{\tilde{Y}}})], \quad (14)$$

and the *L-conditional cross entropy* is defined as

$$H_L(P_Y; P_{\tilde{Y}} | P_X) = \sum_{x \in \mathcal{X}} P_X(x) \mathbb{E}_{Y \sim P_{Y|X=x}} \left[L \left(Y, a_{P_{\tilde{Y} | \tilde{X} = x}} \right) \right]. \quad (15)$$

If the function spaces Λ and Φ are close to each other, the difference between $\text{err}_{\text{inference}}(\delta)$ and the L -conditional cross entropy $H_L \left(P_{Y_t | X_{t-\delta}}; P_{\tilde{Y}_0 | \tilde{X}_{-\delta}} \middle| P_{X_{t-\delta}} \right)$ is small.

Examples of loss function L , L -entropy, and L -cross entropy are provided in Appendix B. Additionally, the definitions of L -divergence $D_L(P_Y || Q_Y)$, L -mutual information $I_L(Y; X)$, and L -conditional mutual information $I_L(Y; X|Z)$ are provided in Appendix C. The relationship among L -divergence, Bregman divergence [38], and f -divergence [39] is discussed in Appendix D.

(a) Training Error vs. AoI (b) Inference Error vs. AoI

Fig. 4: Performance of temperature prediction. The training error and inference error are non-monotonic in AoI. As the feature sequence length u increases, the errors tend closer to non-decreasing functions of the AoI.

B. Training Error vs. Training AoI

We first analyze the monotonicity of L -conditional entropy $H_L(\tilde{Y}_0|\tilde{X}_{-\delta})$ as δ increases. If $\tilde{Y}_0 \leftrightarrow \tilde{X}_{-\mu} \leftrightarrow \tilde{X}_{-\mu-\nu}$ is a Markov chain for all $\mu, \nu \geq 0$, by the data processing inequality for L -conditional entropy [35, Lemma 12.1], $H_L(\tilde{Y}_0|\tilde{X}_{-\delta})$ is a non-decreasing function of δ . Nevertheless, the experimental results in Figs. 1-5 show that the training error is a growing function of the AoI δ in some systems (see Fig. 1), whereas it is a non-monotonic function of δ in other systems (see Figs. 2-5). As we will explain below, a fundamental reason behind these phenomena is that practical time-series data for remote inference could be either Markovian or non-Markovian. For non-Markovian $(\tilde{Y}_0, \tilde{X}_{-\mu}, \tilde{X}_{-\mu-\nu})$, $H_L(\tilde{Y}_0|\tilde{X}_{-\delta})$ is not necessarily monotonic in δ .

We propose a new relaxation of the data processing inequality to analyze information freshness for both Markovian and non-Markovian time-series data. To that end, the following generalization of the standard Markov chain model is needed, which is motivated by the ϵ -dependence concept used in [40].

Definition 1 (ϵ -Markov Chain). Given $\epsilon \geq 0$, a sequence of three random variables Z, X , and Y is said to be an ϵ -Markov chain, denoted as $Z \xrightarrow{\epsilon} X \xrightarrow{\epsilon} Y$, if

$$I_{\log}(Y; Z|X) = D_{\log}(P_{Y,X,Z} \| P_{Y|X} P_{Z|X} P_X) \leq \epsilon^2, \quad (16)$$

where²

$$D_{\log}(P_Y \| Q_Y) = \sum_{y \in \mathcal{Y}} P_Y(y) \log \frac{P_Y(y)}{Q_Y(y)} \quad (17)$$

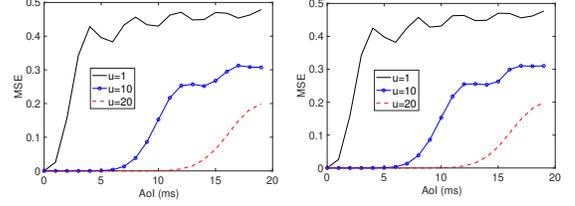

is KL-divergence and $I_{\log}(Y; Z|X)$ is Shannon conditional mutual information.

A Markov chain is an ϵ -Markov chain with $\epsilon = 0$. If $Z \rightarrow X \rightarrow Y$ is a Markov chain, then $Y \rightarrow X \rightarrow Z$ is also a Markov chain [42, p. 34]. A similar property holds for the ϵ -Markov chain.

Lemma 1. If $Z \xrightarrow{\epsilon} X \xrightarrow{\epsilon} Y$, then $Y \xrightarrow{\epsilon} X \xrightarrow{\epsilon} Z$.

Proof. See Appendix G. \square

²In (16), if $P_{Y|X=x}(y) = 0$, then $P_{Y|X=x, Z=z}(y) = 0$ which leads to a term $0 \log \frac{0}{0}$ in the KL-divergence $D_{\log}(P_{Y|X=x, Z=z} \| P_{Y|X=x})$. We adopt the convention in information theory [41] to define $0 \log \frac{0}{0} = 0$.

(a) Training Error vs. AoI (b) Inference Error vs. AoI

Fig. 5: Performance of channel state information (CSI) prediction. The training error and inference error are non-monotonic in AoI. As the feature sequence length u increases, the errors tend closer to non-decreasing functions of the AoI.

By Lemma 1, the ϵ -Markov chain can be denoted as $Y \xleftrightarrow{\epsilon} X \xleftrightarrow{\epsilon} Z$. In the following lemma, we provide a relaxation of the data processing inequality, which is called an ϵ -data processing inequality.

Lemma 2 (ϵ -data processing inequality). The following assertions are true:

(a) If $Y \xleftrightarrow{\epsilon} X \xleftrightarrow{\epsilon} Z$ is an ϵ -Markov chain, then

$$H_L(Y|X) \leq H_L(Y|Z) + O(\epsilon). \quad (18)$$

(b) If, in addition, $H_L(Y)$ is twice differentiable in $\mathcal{P}^{\mathcal{Y}}$, then

$$H_L(Y|X) \leq H_L(Y|Z) + O(\epsilon^2). \quad (19)$$

Proof. Lemma 2 is proven by using a local information geometric analysis. See Appendix H for the details. \square

Lemma 2(b) was mentioned in [43] without proof. Lemma 2(a) is a new result. Now, we are ready to characterize how $H_L(\tilde{Y}_0|\tilde{X}_{-\delta})$ varies with the AoI δ .

Theorem 1. The L -conditional entropy

$$H_L(\tilde{Y}_0|\tilde{X}_{-\delta}) = g_1(\delta) - g_2(\delta) \quad (20)$$

is a function of δ , where $g_1(\delta)$ and $g_2(\delta)$ are two non-decreasing functions of δ , given by

$$g_1(\delta) = H_L(\tilde{Y}_0|\tilde{X}_0) + \sum_{k=0}^{\delta-1} I_L(\tilde{Y}_0; \tilde{X}_{-k}|\tilde{X}_{-k-1}),$$

$$g_2(\delta) = \sum_{k=0}^{\delta-1} I_L(\tilde{Y}_0; \tilde{X}_{-k-1}|\tilde{X}_{-k}), \quad (21)$$

where the L -conditional mutual information $I_L(Y; X|Z)$ between two random variables Y and X given Z is

$$I_L(Y; X|Z) = H_L(Y|Z) - H_L(Y|X, Z). \quad (22)$$

If $\tilde{Y}_0 \xleftrightarrow{\epsilon} \tilde{X}_{-\mu} \xleftrightarrow{\epsilon} \tilde{X}_{-\mu-\nu}$ is an ϵ -Markov chain for every $\mu, \nu \geq 0$, then $g_2(\delta) = O(\epsilon)$ and

$$H_L(\tilde{Y}_0|\tilde{X}_{-\delta}) = g_1(\delta) + O(\epsilon). \quad (23)$$

Proof. See Appendix I. \square

According to Theorem 1, the monotonicity of $H_L(\tilde{Y}_0|\tilde{X}_{-\delta})$ in δ is characterized by the parameter $\epsilon \geq 0$ in the ϵ -Markov chain model. If ϵ is small, then $\tilde{Y}_0 \xleftrightarrow{\epsilon} \tilde{X}_{-\mu} \xleftrightarrow{\epsilon} \tilde{X}_{-\mu-\nu}$ is close

to a Markov chain, and $H_L(\tilde{Y}_0|\tilde{X}_{-\delta})$ is nearly non-decreasing in δ . If ϵ is large, then $\tilde{Y}_0 \xleftrightarrow{\epsilon} \tilde{X}_{-\mu} \xleftrightarrow{\epsilon} \tilde{X}_{-\mu-\nu}$ is far from a Markov chain, and $H_L(\tilde{Y}_0|\tilde{X}_{-\delta})$ could be non-monotonic in δ . Theorem 1 can be readily extended to the training error with random AoI Θ by using stochastic orders [44].

Definition 2 (Univariate Stochastic Ordering). [44] *A random variable X is said to be stochastically smaller than another random variable Z , denoted as $X \leq_{st} Z$, if*

$$P(X > x) \leq P(Z > x), \quad \forall x \in \mathbb{R}. \quad (24)$$

Theorem 2. *If $\tilde{Y}_0 \xleftrightarrow{\epsilon} \tilde{X}_{-\mu} \xleftrightarrow{\epsilon} \tilde{X}_{-\mu-\nu}$ is an ϵ -Markov chain for all $\mu, \nu \geq 0$, and the training AoIs in two experiments 1 and 2 satisfy $\Theta_1 \leq_{st} \Theta_2$, then*

$$H_L(\tilde{Y}_0|\tilde{X}_{-\Theta_1}, \Theta_1) \leq H_L(\tilde{Y}_0|\tilde{X}_{-\Theta_2}, \Theta_2) + O(\epsilon). \quad (25)$$

Proof. See Appendix J. \square

According to Theorem 2, if Θ_1 is stochastically smaller than Θ_2 , then the training error in Experiment 1 is approximately smaller than that in Experiment 2. If, in addition to the conditions in Theorems 1-2, $H_L(\tilde{Y}_0)$ is twice differentiable in $P_{\tilde{Y}_0}$, then the last term $O(\epsilon)$ in (23) and (25) becomes $O(\epsilon^2)$.

C. Inference Error vs. Inference AoI

Using (8), (9), and (15), it is easy to show that the L -conditional cross entropy $H_L(P_{Y_t|X_{t-\delta}}; P_{\tilde{Y}_0|\tilde{X}_{-\delta}}|P_{X_{t-\delta}})$ is lower bounded by the L -conditional entropy $H_L(Y_t|X_{t-\delta})$. In addition, $H_L(P_{Y_t|X_{t-\delta}}; P_{\tilde{Y}_0|\tilde{X}_{-\delta}}|P_{X_{t-\delta}})$ is close to its lower bound $H_L(Y_t|X_{t-\delta})$, if the conditional distributions $P_{Y_t|X_{t-\delta}}$ and $P_{\tilde{Y}_0|\tilde{X}_{-\delta}}$ are close to each other, as stated in Lemma 3.

Lemma 3. *Given $\beta \geq 0$, if for all $\delta \in \mathbb{Z}^+$*

$$\sum_{x \in \mathcal{X}} P_{X_{t-\delta}}(x) \sum_{y \in \mathcal{Y}} (P_{Y_t|X_{t-\delta}=x}(y) - P_{\tilde{Y}_0|\tilde{X}_{-\delta}=x}(y))^2 \leq \beta^2, \quad (26)$$

then for all $\delta \in \mathbb{Z}^+$

$$H_L(P_{Y_t|X_{t-\delta}}; P_{\tilde{Y}_0|\tilde{X}_{-\delta}}|P_{X_{t-\delta}}) = H_L(Y_t|X_{t-\delta}) + O(\beta). \quad (27)$$

Proof. See Appendix K. \square

Combining Theorem 1 and Lemma 3, the monotonicity of $H_L(P_{Y_t|X_{t-\delta}}; P_{\tilde{Y}_0|\tilde{X}_{-\delta}}|P_{X_{t-\delta}})$ versus δ is characterized in the next theorem.

Theorem 3. *If $Y_t \xleftrightarrow{\epsilon} X_{t-\mu} \xleftrightarrow{\epsilon} X_{t-\mu-\nu}$ is an ϵ -Markov chain for all $\mu, \nu \geq 0$ and (26) holds for all $\delta \in \mathbb{Z}^+$, then for all $0 \leq \delta_1 \leq \delta_2$*

$$\begin{aligned} & H_L(P_{Y_t|X_{t-\delta_1}}; P_{\tilde{Y}_0|\tilde{X}_{-\delta_1}}|P_{X_{t-\delta_1}}) \\ & \leq H_L(P_{Y_t|X_{t-\delta_2}}; P_{\tilde{Y}_0|\tilde{X}_{-\delta_2}}|P_{X_{t-\delta_2}}) + O(\max\{\epsilon, \beta\}). \end{aligned} \quad (28)$$

Proof. See Appendix L. \square

According to Theorem 3, if ϵ and β are close to zero, $H_L(P_{Y_t|X_{t-\delta}}; P_{\tilde{Y}_0|\tilde{X}_{-\delta}}|P_{X_{t-\delta}})$ is nearly a non-decreasing function of δ ; otherwise, $H_L(P_{Y_t|X_{t-\delta}}; P_{\tilde{Y}_0|\tilde{X}_{-\delta}}|P_{X_{t-\delta}})$ as a function of δ can be non-monotonic.

D. Interpretation of the Experimental Results

We use Theorems 1-3 to interpret the experimental results in Figs. 1-5. In Fig. 1, the training and inference errors for video prediction are increasing functions of the AoI. This observation suggests that the target and feature time-series data $(Y_t, X_{t-\mu}, X_{t-\mu-\nu})$ for video prediction is close to a Markov chain. In the robot state prediction experiment depicted in Fig. 2, the state of the follower robot depends on the state of the leader robot received through a channel. Due to the communication delay from the leader robot to the follower robot, the target and feature data sequence $(Y_t, X_{t-\mu}, X_{t-\mu-\nu})$ can be far from a Markov chain. In the experiment of actuator state prediction under mechanical response delay, pole angle at time t is strongly correlated with the cart velocity generated 25 ms ago, as observed from data traces in Fig. 3(b). Moreover, temperature and CSI signals have long-range dependence. For example, temperature at time t depends on the temperature of 24 hours ago. These observations imply that the target and feature data sequence $(Y_t, X_{t-\mu}, X_{t-\mu-\nu})$ for all $\mu, \nu \geq 0$ may not be close to a Markov chain in the experimental results depicted in Figs. 2-5. Because the target and feature time-series data involved is non-Markovian, Theorems 1-3 suggest that the training error and inference error could be non-monotonic with respect to AoI, as observed in Figs. 2-5.

Recall that u is the sequence length of the feature $X_t = (V_t, V_{t-1}, \dots, V_{t-u+1})$. In Figs. 3-5, the training and inference errors tends to become non-decreasing functions of the AoI δ as the feature length u grows. This phenomenon can be interpreted by Theorems 1-3: According to Shannon's Markovian representation of discrete-time sources in his seminal work [45], the larger u , the closer $(Y_t, X_{t-\mu}, X_{t-\mu-\nu})$ tends to a Markov chain. According to Theorems 1-3, as u increases, the training and inference errors tend to be non-decreasing with respect to the AoI δ , which agrees with Figs. 3-5. One disadvantage of large feature length u is that it increases the channel resources needed for transmitting the features. The optimal choice of the feature length u is studied in [46].

IV. A MODEL-BASED INTERPRETATION OF INFORMATION FRESHNESS IN REMOTE INFERENCE

We construct two models to analyze the non-monotonicity of the L -conditional entropy $H_L(Y_t|X_{t-\delta})$ with respect to the AoI δ and interpret the reasons.

A. Reaction Prediction with Delay

To facilitate understanding of the counter-intuitive experimental results illustrated in Figs. 2-3, we present the following analytical example for reaction prediction.

Example 1 (Reaction Prediction). *Consider a causal system represented by $Y_t = f(X_{t-d})$, where X_t and Y_t are the input and output of the system, respectively, $d \geq 0$ is the delay introduced by the system, and $f(\cdot)$ is a function.*

Lemma 4. *If X_t is a Markov chain and $Y_t = f(X_{t-d})$, then $H_L(Y_t|X_{t-\delta})$ decreases with δ when $0 \leq \delta \leq d$ and increases with δ when $\delta \geq d$. In addition, for any random variable Z ,*

$$H_L(Y_t|X_{t-d}) = H_L(Y_t|Y_t) \leq H_L(Y_t|Z). \quad (29)$$

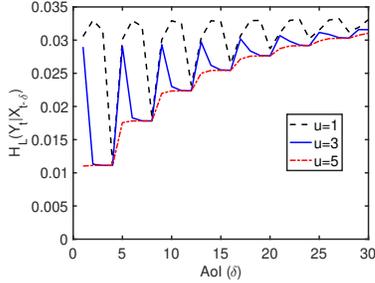

Fig. 6: L -conditional entropy vs. AoI for Example 2.

Proof. See Appendix Q. \square

Lemma 4 implies that the feature X_{t-d} achieves the minimum expected loss in predicting Y_t . Therefore, for predicting Y_t , X_{t-d} is the optimal choice, not the freshest feature X_t . Hence, fresh data is not always the best.

The robotic state prediction and the actuator state prediction experiments in Figs. 2-3 are also instances of reaction prediction. Similar to Example 1, the freshest feature with AoI=0 is not the best choice for predicting the reaction in Figs. 2-3. However, the relationship between the leader and follower robots' states in the robotic state prediction experiment and the relationship between cart velocity and pole angle in the actuator state prediction experiment are much more complicated than the input-output relationship in Example 1.

B. Autoregressive Model

We evaluate the L -conditional entropy using an autoregressive linear system model.

Example 2 (Autoregressive Model). Consider a discrete time autoregressive linear system of the order 4, i.e., AR(4):

$$V_t = 0.1V_{t-1} + 0.4V_{t-4} + W_t, \quad (30)$$

where $W_t \in \mathbb{R}$ is a Gaussian noise with zero mean and variance 0.01. Let $Y_t = V_t + N_t$ be the target variable, where N_t is a Gaussian noise with zero mean and variance 0.01. Both W_t and N_t are i.i.d. over time. The goal is to predict Y_t using a feature sequence $X_{t-\delta} = (V_{t-\delta}, V_{t-\delta-1}, \dots, V_{t-\delta-u+1})$ with length u . The prediction error is characterized by a quadratic loss function $L(y, \hat{y}) = (y - \hat{y})^2$. Because (i) $X_{t-\delta}$ and Y_t are jointly Gaussian and (ii) the loss function is quadratic, the L -conditional entropy $H_L(Y_t|X_{t-\delta}) = \mathbb{E}[(Y_t - \mathbb{E}[Y_t|X_{t-\delta}])^2]$ is the linear minimum mean-square error in signal-agnostic remote estimation.

We can observe from Fig. 6 that the L -conditional entropy is non-monotonic in the AoI δ when the feature length is $u = 1$ or 3. When u is increased to 5, $H_L(Y_t|X_{t-\delta})$ becomes a non-decreasing function of the AoI δ . This is because $Y_t \leftrightarrow X_{t-\mu} \leftrightarrow X_{t-\mu-\nu}$ is a Markov chain when $u = 5$. The model-based numerical evaluation results in Fig. 6 is similar to the experimental results in Figs. 3-5. In general, $H_L(Y_t|X_{t-\delta})$ for any AR(p) model with $p \geq 2$ can be non-monotonic in AoI δ ,

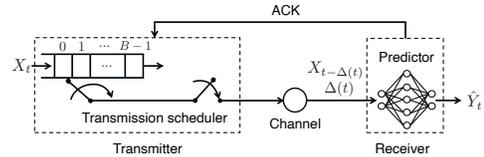

Fig. 7: A remote inference system with “selection-from-buffer.” At each time slot t , the transmitter generates a feature X_t and keeps it in a buffer that stores B most recent features $(X_t, X_{t-1}, \dots, X_{t-B+1})$. The scheduler decides (i) when to submit features to the channel and (ii) which feature in the buffer to submit.

particularly when the feature length u is small. In a follow-up study [47], we provide analytical expressions of the L -conditional entropy and the parameter ϵ for the AR(p) model.

V. SCHEDULING FOR INFERENCE ERROR MINIMIZATION: THE SINGLE-SOURCE, SINGLE-CHANNEL CASE

In this section, we will introduce a new “selection-from-buffer” medium access model and develop a novel transmission scheduling policy to minimize the time-average inference error in single-source remote inference systems. This scheduling policy can effectively minimize general functions of the AoI, regardless of whether the function is monotonic or not.

A. Selection-from-Buffer: A New Status Updating Model

Consider the remote inference system depicted in Fig. 7, where a source progressively generates features and sends them through a channel to a receiver. The system operates in discrete time-slots. In each time slot t , a pre-trained neural network at the receiver employs the freshest received feature $X_{t-\Delta(t)}$ to infer the current label Y_t .

As discussed in Sections II-III, the inference error $\text{err}_{\text{inference}}(\Delta(t))$ is a function of the AoI $\Delta(t)$, whereas the function is not necessarily monotonically increasing. In certain scenarios, a stale feature with $\Delta(t) > 0$ can outperform a freshly generated feature with $\Delta(t) = 0$. Inspired by these observations, we introduce a novel medium access model for status updating, which is termed the “selection-from-buffer” model. In this model, the source maintains a buffer that stores the B most recent features $(X_t, X_{t-1}, \dots, X_{t-B+1})$ in each time slot t . Specifically, at the beginning of time slot t , the source appends a newly generated feature X_t to the buffer, while concurrently evicting the oldest feature X_{t-B} . If the channel is available at time slot t , the transmitter can send one of the B most recent features or remain silent, where the transmission may last for one or multiple time-slots. Notably, the “selection-from-buffer” model generalizes the “generate-at-will” model [4], [6], with the latter is a special case of the former with $B = 1$.³

The system starts to operate at time slot $t = 0$. We assume that the buffer is initially populated with B features

³In comparison to the “generate-at-will” model, our “selection-from-buffer” model presents a critical advantage: it enables the systematic investigation of optimal feature design for remote inference. As an evidence, our subsequent study [46] demonstrates that substantial performance improvements can be attained through the joint optimization of transmission scheduling and the feature sequence length u .

$(X_0, X_{-1}, \dots, X_{-B+1})$ at time slot $t = 0$. By this, the buffer is kept full at all time slot $t \geq 0$. The channel is modeled as a non-preemptive server with feature transmission times $T_i \geq 1$, which can be random due to factors like time-varying channel conditions, collisions, random packet sizes, etc. We assume that the T_i 's are *i.i.d.* with $1 \leq \mathbb{E}[T_i] < \infty$. The i -th feature is generated in time slot G_i , submitted to the channel in time slot S_i , and delivered to the receiver in time slot $D_i = S_i + T_i$, where $G_i \leq S_i < D_i$, and $D_i \leq S_{i+1} < D_{i+1}$. Once a feature is delivered, an acknowledgment (ACK) is fed back to the transmitter in the same time slot. Thus, the idle/busy state of the channel is known at the transmitter.

B. Scheduling Policies and Problem Formulation

A transmission scheduler determines (i) when to submit features to the channel and (ii) which feature in the buffer to submit. In time slot S_i , let $X_{G_i} = X_{S_i - b_i}$ be the feature submitted to the channel, which is the $(b_i + 1)$ -th freshest feature in the buffer, with $b_i \in \{0, 1, \dots, B - 1\}$. By this, $G_i = S_i - b_i$. A scheduling policy is denoted by a 2-tuple (f, g) , where $g = (S_1, S_2, \dots)$ determines when to submit the features and $f = (b_1, b_2, \dots)$ specifies which feature in the buffer to submit.

Let $U(t) = \max_i \{G_i : D_i \leq t\}$ represent the generation time of the freshest feature delivered to the receiver up to time slot t . Because $G_i = S_i - b_i$, $U(t) = \max_i \{S_i - b_i : D_i \leq t\}$. The age of information (AoI) at time t is [3]

$$\Delta(t) = t - U(t) = t - \max_i \{S_i - b_i : D_i \leq t\}. \quad (31)$$

Because $D_i < D_{i+1}$, $\Delta(t)$ can be re-written as

$$\Delta(t) = t - S_i + b_i, \quad \text{if } D_i \leq t < D_{i+1}. \quad (32)$$

The initial state of the system is assumed to be $S_0 = 0, D_0 = T_0$, and $\Delta(0)$ is a finite constant.

We focus on the class of *signal-agnostic* scheduling policies in which each decision is determined without using the knowledge of the signal value of the observed process. A scheduling policy (f, g) is said to be signal-agnostic, if the policy is independent of $\{(Y_t, X_t), t = 0, 1, 2, \dots\}$. Let Π represent the set of all causal and signal-agnostic scheduling policies that satisfy three conditions: (i) the transmission time schedule S_i and the buffer position b_i are determined based on the current and the historical information available at the scheduler; (ii) the scheduler does not have access to the realization of the process $\{(Y_t, X_t), t = 0, 1, 2, \dots\}$; and (iii) the scheduler can access the inference error function $\text{err}_{\text{inference}}(\cdot)$ and the distribution of T_i .

Our goal is to find an optimal scheduling policy that minimizes the time-average expected inference error among all causal scheduling policies in Π :

$$\bar{p}_{opt} = \inf_{(f,g) \in \Pi} \limsup_{T \rightarrow \infty} \frac{1}{T} \mathbb{E}_{(f,g)} \left[\sum_{t=0}^{T-1} p(\Delta(t)) \right]. \quad (33)$$

where we use a simpler notation $p(\Delta(t)) = \text{err}_{\text{inference}}(\Delta(t))$ to represent the inference error in time-slot t , and \bar{p}_{opt} is the optimum value of (33). Because $p(\cdot)$ is not necessarily monotonic and the scheduler needs to determine which

feature in the buffer to send, (33) is more challenging than the scheduling problems for minimizing non-decreasing age functions in [4]–[16]. Note that $p(\Delta(t)) = \text{err}_{\text{inference}}(\Delta(t))$ is the inference error in time-slot t , instead of its information-theoretic approximations.

C. An Optimal Scheduling Solution

To elucidate the optimal solution to the scheduling problem (33), we first fix the buffer position at $b_i = b$ for each feature i submitted to the channel and focus on the optimization of the transmission time schedule $g = (S_1, S_2, \dots)$. This simplified transmission scheduling problem is expressed as

$$\bar{p}_{b,opt} = \inf_{(f_b,g) \in \Pi} \limsup_{T \rightarrow \infty} \frac{1}{T} \mathbb{E}_{(f_b,g)} \left[\sum_{t=0}^{T-1} p(\Delta(t)) \right], \quad (34)$$

where $f_b = (b, b, \dots)$ represents an invariant buffer position assignment policy and $\bar{p}_{b,opt}$ is the optimal objective value in (34). The insights gained from solving this simplified problem (34) will subsequently guide us in deriving the optimal solution to the original scheduling problem (33).

Theorem 4. *If $|p(\delta)| \leq M$ for all δ and the T_i 's are *i.i.d.* with $1 \leq \mathbb{E}[T_i] < \infty$, then $g = (S_1(\beta_b), S_2(\beta_b), \dots)$ is an optimal solution to (34), where*

$$S_{i+1}(\beta_b) = \min_{t \in \mathbb{Z}} \{t \geq D_i(\beta_b) : \gamma(\Delta(t)) \geq \beta_b\}, \quad (35)$$

$D_i(\beta_b) = S_i(\beta_b) + T_i$ is the delivery time of the i -th feature submitted to the channel, $\Delta(t) = t - S_i(\beta_b) + b$ is the AoI at time t , $\gamma(\delta)$ is an index function, defined by

$$\gamma(\delta) = \inf_{\tau \in \{1, 2, \dots\}} \frac{1}{\tau} \sum_{k=0}^{\tau-1} \mathbb{E}[p(\delta + k + T_1)], \quad (36)$$

and the threshold β_b is the unique root of

$$\mathbb{E} \left[\sum_{t=D_i(\beta_b)}^{D_{i+1}(\beta_b)-1} p(\Delta(t)) \right] - \beta_b \mathbb{E}[D_{i+1}(\beta_b) - D_i(\beta_b)] = 0. \quad (37)$$

The optimal objective value to (34) is given by

$$\bar{p}_{b,opt} = \frac{\mathbb{E} \left[\sum_{t=D_i(\beta_b)}^{D_{i+1}(\beta_b)-1} p(\Delta(t)) \right]}{\mathbb{E}[D_{i+1}(\beta_b) - D_i(\beta_b)]}. \quad (38)$$

Furthermore, β_b is equal to the optimal objective value to (34), i.e., $\beta_b = \bar{p}_{b,opt}$.

Proof sketch. The scheduling problem (34) is an infinite-horizon average-cost semi-Markov decision process (SMDP) [48, Chapter 5.6]. Define $\tau = S_{i+1} - D_i$ as the waiting time for sending the $(i+1)$ -th feature after the i -th feature is delivered. The Bellman optimality equation of the SMDP (34) is

$$h_b(\delta) = \inf_{\tau \in \{0, 1, 2, \dots\}} \mathbb{E} \left[\sum_{k=0}^{\tau+T_i-1} (p(\delta + k) - \bar{p}_{b,opt}) \right] + \mathbb{E}[h_b(T_i + b)], \quad \delta = 1, 2, \dots, \quad (39)$$

where $h_b(\cdot)$ is the relative value function of the SMDP (34). Theorem 4 is proven by directly solving (39). The details are provided in Appendix M. \square

In supervised learning algorithms, features are shifted, rescaled, and clipped during data pre-processing. Because of these pre-processing techniques, the inference error $p(\delta)$ is bounded, as illustrated in Figs. 1-5. Therefore, the assumption $|p(\delta)| \leq M$ for all δ in Theorem 4 is not restrictive in practice.

The optimal scheduling policy in Theorem 4 is a threshold policy described by the index function $\gamma(\delta)$: According to (35), a feature is transmitted in time-slot t if and only if two conditions are satisfied: (i) The channel is available for scheduling in time-slot t and (ii) the index $\gamma(\Delta(t))$ exceeds a threshold β_b , which is precisely equal to the optimal objective value $\bar{p}_{b,opt}$ of (34). The expression of $\gamma(\delta)$ in (36) is obtained by solving the Bellman optimality equation (39), as explained in Appendix M. The threshold β_b is calculated by solving the unique root of (37). Three low-complexity algorithms for this purpose were given by [9, Algorithms 1-3].

It is crucial to note that a non-monotonic AoI function $p(\delta)$ often leads to a non-monotonic index function $\gamma(\delta)$. Consequently, the inverse function of $\gamma(\delta)$ may not exist and the inequality $\gamma(\Delta(t)) \geq \beta_b$ in the threshold policy (35) cannot be equivalently rewritten as an inequality of the form $\Delta(t) \geq \alpha$. This distinction represents a significant departure from previous studies for minimizing either the AoI $\Delta(t)$ or its non-decreasing functions, e.g., [4]–[16]. In these earlier works, the solutions were usually expressed as threshold policies in the form $\Delta(t) \geq \alpha$. Our pursuit of a simple threshold policy for minimizing general and potentially non-monotonic AoI functions was inspired by the restart-in-state formulation of the Gittins index [49, Chapter 2.6.4], [50].

Now we present an optimal solution to (33).

Theorem 5. *If the conditions of Theorem 4 hold, then an optimal solution (f^*, g^*) to (33) is determined by*

(a) $f^* = (b^*, b^*, \dots)$, where

$$b^* = \arg \min_{b \in \{0, 1, \dots, B-1\}} \bar{p}_{b,opt}, \quad (40)$$

and $\bar{p}_{b,opt}$ is the optimal objective value to (34).

(b) $g^* = (S_1^*, S_2^*, \dots)$, where

$$S_{i+1}^* = \min_{t \in \mathbb{Z}} \{t \geq D_i^* : \gamma(\Delta(t)) \geq \bar{p}_{opt}\}, \quad (41)$$

$D_i^* = S_i^* + T_i$, $\gamma(\delta)$ is defined in (36), and \bar{p}_{opt} is the optimal objective value of (33), given by

$$\bar{p}_{opt} = \min_{b \in \{0, 1, \dots, B-1\}} \bar{p}_{b,opt}. \quad (42)$$

Proof. See Appendix M. \square

Theorem 5 suggests that, in the optimal solution to (33), one should select features from a fixed buffer position $b_i = b^*$. In addition, a feature is transmitted in time-slot t if and only if two conditions are satisfied: (i) The channel is available for transmission in time-slot t , (ii) the index $\gamma(\Delta(t))$ exceeds a threshold \bar{p}_{opt} (i.e., $\gamma(\Delta(t)) \geq \bar{p}_{opt}$), where the threshold \bar{p}_{opt} is exactly the optimal objective value of (33).

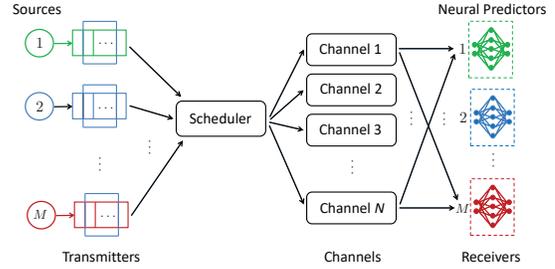

Fig. 8: A multi-source, multi-channel remote inference system.

In the special case of a non-decreasing AoI function $p(\delta)$, it can be shown that the index function $\gamma(\delta) = \mathbb{E}[p(\delta + T_1)]$ is non-decreasing and $b^* = 0$ is the optimal buffer position in (40). The optimal strategy in such cases is to consistently select the freshest feature from the buffer such that $b_i = 0$. Hence, both the “generate-at-will” and “selection-from-buffer” models achieve the same minimum inference error. Furthermore, Theorem 3 in [7] can be directly derived from Theorem 5.

VI. SCHEDULING FOR INFERENCE ERROR MINIMIZATION: THE MULTI-SOURCE, MULTI-CHANNEL CASE

In this section, we develop a novel transmission scheduling policy to minimize the weighted summation inference error in multi-source, multi-channel remote inference systems.

A. Multi-source, Multi-channel Status Updating Model

Consider the remote inference system depicted in Fig. 8, which consists of M source-predictor pairs and N channels. Each source adopts a “selection-from-buffer” model: At the beginning of time slot t , each source m generates a feature $X_{m,t}$ and adds it into the buffer that stores B_m most recent features $(X_{m,t}, \dots, X_{m,t-B_m+1})$, meanwhile the oldest feature $X_{m,t-B_m}$ is removed from the buffer. At each time slot t , a central scheduler decides: (i) which sources to select and (ii) which features from the buffer of selected sources to send. Each feature transmission lasts for one or multiple time slots. We consider non-preemptive transmissions, i.e., once a channel starts to send a feature, the channel must finish serving that feature before switching to serve another feature. At any given time slot, each source can be served by no more than one channel. We use an indicator variable $c_m(t) \in \{0, 1\}$ to represent whether a feature from source m occupies a channel at time slot t , where $c_m(t) = 1$ if source m is being served by a channel at time slot t ; otherwise, $c_m(t) = 0$. Once a feature is delivered, an acknowledgment is fed back to the scheduler within the same time-slot. By this, the channel occupation status $c_m(t)$ is known to the scheduler at every time slot t . Due to limited channel resources, the system must satisfy the constraint $\sum_{m=1}^M c_m(t) \leq N$ for all time slot $t = 0, 1, \dots$

The system starts to operate at time slot $t = 0$. The i -th feature sent by source m is generated in time slot $G_{m,i}$, submitted to a channel in time slot $S_{m,i}$, and delivered to the receiver in time slot $D_{m,i} = S_{m,i} + T_{m,i}$, where $G_{m,i} \leq S_{m,i} < D_{m,i}$, $D_{m,i} \leq S_{m,i+1} < D_{m,i+1}$, and $T_{m,i} \geq 1$ is the feature transmission time. We assume that the $T_{m,i}$'s are independent across the sources and are i.i.d. for features originating from the same source with $1 \leq \mathbb{E}[T_{m,i}] < \infty$.

B. Scheduling Policies and Problem Formulation

In time slot $S_{m,i}$, let $X_{G_{m,i}} = X_{S_{m,i}-b_{m,i}}$ be the feature submitted to a channel from source m , which is the $(b_{m,i}+1)$ -th freshest feature in source m 's buffer, with $b_{m,i} \in \{0, 1, \dots, B_m - 1\}$. By this, a scheduling policy for source m is denoted by (f_m, g_m) , where $g_m = (S_{m,1}, S_{m,2}, \dots)$ determines when to schedule source m , and $f_m = (b_{m,1}, b_{m,2}, \dots)$ specifies which feature to send from source m 's buffer.

Let $U_m(t) = \max_i \{G_{m,i} : D_{m,i} \leq t\}$ represent the generation time of the freshest feature delivered from source m to the receiver up to time slot t . Because $G_{m,i} = S_{m,i} - b_{m,i}$, $U_m(t) = \max_i \{S_{m,i} - b_{m,i} : D_{m,i} \leq t\}$. The age of information (AoI) of source m at time slot t is

$$\Delta_m(t) = t - U_m(t) = t - \max_i \{S_{m,i} - b_{m,i} : D_{m,i} \leq t\}. \quad (43)$$

The initial state of the system is assumed to be $S_{m,0} = 0$, $D_{m,0} = T_{m,0}$, and $\Delta_m(0)$ is a finite constant.

Let Π_m denote the set of all causal and signal-agnostic scheduling policies (f_m, g_m) that satisfy the following conditions: (i) the transmission time schedule $S_{m,i}$ and the buffer position $b_{m,i}$ are determined based on the current and the historical information available at the scheduler; (ii) source m can be served by at most one channel at a time and feature transmissions are non-preemptive; (iii) the scheduler does not have access to the realization of the feature and the target processes; and (iv) the scheduler can access the inference error function $\text{err}_{\text{inference},m}(\Delta_m(t))$ and the distribution of $T_{m,i}$ for source m . We define Π as the set of all causal and signal-agnostic scheduling policies $\pi = (f_m, g_m)_{m=1}^M$.

Our goal is to find a scheduling policy that minimizes the weighted summation of the time-averaged expected inference errors of the M sources:

$$\inf_{\pi \in \Pi} \limsup_{T \rightarrow \infty} \sum_{m=1}^M w_m \mathbb{E} \left[\frac{1}{T} \sum_{t=0}^{T-1} p_m(\Delta_m(t)) \right], \quad (44)$$

$$\text{s.t.} \quad \sum_{m=1}^M c_m(t) \leq N, t = 0, 1, \dots, \quad (45)$$

$$c_m(t) \in \{0, 1\}, m = 1, 2, \dots, M, t = 0, 1, \dots, \quad (46)$$

where $p_m(\Delta_m(t)) = \text{err}_{\text{inference},m}(\Delta_m(t))$ is the inference error of source m at time slot t and $w_m > 0$ is the weight of source m .

Let $d_m(t) \in \{0, 1, \dots\}$ denote the amount of time that has been spent to send the current feature of source m by time slot t . Hence, $d_m(t) = 0$ if no feature of source m is in service at time slot t , and $d_m(t) > 0$ if a feature of source m is currently in service at time slot t . Problem (44)-(46) is a multi-action Restless Multi-armed Bandit (RMAB) problem, in which $(\Delta_m(t), d_m(t))$ is the state of the m -th bandit. At time slot t , if a feature from source m is submitted to a channel, bandit m is said to be *active*; otherwise, if source m is not under service or if one feature of source m is under service whereas the service started before time slot t , then bandit m is said to be *passive*. The bandits are "restless" because the state $(\Delta_m(t), d_m(t))$ undergoes changes even when the m -th bandit is passive [10], [29]. When a bandit m is activated, the

scheduler can select any of the B_m features from the buffer of source m . Thus, this problem is a multi-action RMAB.

It is well-known that RMAB with binary actions is PSPACE-hard [51]. RMABs with multiple actions, like (44)-(46), would be even more challenging to solve. In the sequence, we will generalize the conventional Whittle index theoretical framework [29] for binary-action RMABs, by developing a new index-based scheduling policy and proving this policy is asymptotically optimal for solving the multi-action RMAB problem (44)-(46). This new theoretical framework contains four steps: (a) We first reformulate (44)-(46) as an equivalent multi-action RMAB problem with an equality constraint by using dummy bandits [17], [24]. The usage of dummy bandits is necessary for establishing the asymptotic optimality result in subsequent steps. (b) We relax the per-time-slot channel constraint as a time-average expected channel constraint, solve the relaxed problem by using Lagrangian dual optimization, and compute the optimal dual variable λ^* . (c) Problem (44)-(46) requires to determine (i) which source to schedule and (ii) which feature from the buffer of the scheduled source to send. In the proposed scheduling policy, the former is decided by a Whittle index policy, for which we establish indexability and derive an analytical expression of the Whittle index. The latter is determined by a λ^* -based selection-from-buffer policy. (d) Finally, we employ LP priority-based sufficient condition [17], [18] to prove that the proposed policy is asymptotically optimal as the numbers of users and channels increase to infinite with a fixed ratio.

C. Dummy Bandits and Constraint Relaxation

Besides the original M bandits, we introduce N additional *dummy bandits* that satisfy two conditions: (i) each dummy bandit has a zero age penalty function $p_0(\Delta_0(t)) = 0$; (ii) when activated, each dummy bandit occupies a channel. Let $c_0(t) \in \{0, 1, \dots, N\}$ be the number of dummy bandits that are activated in time slot t . Let $\pi_0 = \{c_0(t), t = 0, 1, \dots\}$ be a scheduling policy for the dummy bandits and Π_0 be the set of all policies π_0 . Using these dummy bandits, (44)-(46) is reformulated as an RMAB with equality constraints (48), i.e.,

$$\inf_{\pi \in \Pi, \pi_0 \in \Pi_0} \limsup_{T \rightarrow \infty} \sum_{m=1}^M w_m \mathbb{E} \left[\frac{1}{T} \sum_{t=0}^{T-1} p_m(\Delta_m(t)) \right], \quad (47)$$

$$\text{s.t.} \quad \sum_{m=0}^M c_m(t) = N, t = 0, 1, \dots, \quad (48)$$

$$c_0(t) \in \{0, 1, \dots, N\}, t = 0, 1, \dots, \quad (49)$$

$$c_m(t) \in \{0, 1\}, m = 1, 2, \dots, M, t = 0, 1, \dots \quad (50)$$

Now, we replace the per-slot channel constraints (48) by a time-average expected channel constraint (52), which produces

the following relaxed problem:

$$\inf_{\pi \in \Pi, \pi_0 \in \Pi_0} \limsup_{T \rightarrow \infty} \sum_{m=1}^M w_m \mathbb{E} \left[\sum_{t=0}^{T-1} p_m(\Delta_m(t)) \right], \quad (51)$$

$$\text{s.t. } \limsup_{T \rightarrow \infty} \sum_{m=0}^M \mathbb{E} \left[\frac{1}{T} \sum_{t=0}^{T-1} c_m(t) \right] = N, \quad (52)$$

$$c_0(t) \in \{0, 1, \dots, N\}, t = 0, 1, \dots, \quad (53)$$

$$c_m(t) \in \{0, 1\}, m = 1, 2, \dots, M, t = 0, 1, \dots \quad (54)$$

The optimal objective value of (51)-(54) provides a lower bound of the optimal objective value of (44)-(46).

D. Lagrangian Dual Optimization for Solving (51)-(54)

We solve the relaxed problem (51)-(54) by Lagrangian dual optimization [29], [52]. To that end, we associate a Lagrangian multiplier $\lambda \in \mathbb{R}$ to the constraint (52) and get the following dual function

$$q(\lambda) = \inf_{\pi \in \Pi, \pi_0 \in \Pi_0} \limsup_{T \rightarrow \infty} \mathbb{E} \left[\frac{1}{T} \sum_{t=0}^{T-1} \left(\sum_{m=1}^M w_m p_m(\Delta_m(t)) + \lambda \left(\sum_{m=0}^M c_m(t) - N \right) \right) \right], \quad (55)$$

where $\lambda \in \mathbb{R}$ is also referred to as the transmission cost. The dual optimization problem is given by

$$\lambda^* = \arg \max_{\lambda \in \mathbb{R}} q(\lambda), \quad (56)$$

where λ^* is the optimal dual solution.

1) *Solution to (55)*: The problem (55) can be decomposed into $(M + 1)$ sub-problems. For $m = 0$, the sub-problem associated to the dummy bandits is given by

$$\inf_{\pi_0 \in \Pi_0} \limsup_{T \rightarrow \infty} \mathbb{E}_{\pi_0} \left[\frac{1}{T} \sum_{t=0}^{T-1} \lambda c_0(t) \right]. \quad (57)$$

Theorem 6. *If $\lambda > 0$, the optimal solution to (57) is $c_0^*(t) = 0$ for all t ; if $\lambda \leq 0$, the optimal solution to (57) is $c_0^*(t) = N$ for all t .*

For each $m = 1, 2, \dots, M$, the sub-problem associated with bandit m is given by

$$\begin{aligned} & \bar{p}_{m,opt}(\lambda) \\ &= \inf_{(f_m, g_m) \in \Pi_m} \limsup_{T \rightarrow \infty} \mathbb{E} \left[\frac{1}{T} \sum_{t=0}^{T-1} w_m p_m(\Delta_m(t)) + \lambda c_m(t) \right], \quad (58) \end{aligned}$$

where $\bar{p}_{m,opt}(\lambda)$ is the optimal objective value to (58).

To explain the optimal solution to (58), we first fix the buffer position at $b_{m,i} = b$ for all i and optimize the transmission time schedule $g_m = (S_{m,1}, S_{m,2}, \dots)$. This simplified problem is formulated as

$$\begin{aligned} & \bar{p}_{m,b,opt}(\lambda) \\ &= \inf_{(f_m, b, g_m) \in \Pi_m} \limsup_{T \rightarrow \infty} \mathbb{E} \left[\frac{1}{T} \sum_{t=0}^{T-1} w_m p_m(\Delta_m(t)) + \lambda c_m(t) \right], \quad (59) \end{aligned}$$

where $f_{m,b} = (b, b, \dots)$ and $\bar{p}_{m,b,opt}(\lambda)$ is the optimal objective value in (59).

Theorem 7. *If $T_{m,i}$'s are i.i.d. with $1 \leq \mathbb{E}[T_{m,i}] < \infty$, then $g_m(\lambda) = (S_{m,1}(\beta_{m,b}(\lambda)), S_{m,2}(\beta_{m,b}(\lambda)), \dots)$ is an optimal solution to (59), where*

$$\begin{aligned} & S_{m,i+1}(\beta_{m,b}(\lambda)) \\ &= \min_{t \in \mathbb{Z}} \{t \geq D_{m,i}(\beta_{m,b}(\lambda)) : \gamma_m(\Delta_m(t)) \geq \beta_{m,b}(\lambda)\}, \quad (60) \end{aligned}$$

$D_{m,i}(\beta_{m,b}(\lambda)) = S_{m,i}(\beta_{m,b}(\lambda)) + T_{m,i}$ is the delivery time of the i -th feature submitted to the channel, $\Delta_m(t) = t - S_{m,i}(\beta_{m,b}(\lambda)) + b$ is the AoI at time t , $\gamma_m(\delta)$ is an index function, defined by

$$\gamma_m(\delta) = \inf_{\tau \in \{1, 2, \dots\}} \frac{1}{\tau} \sum_{k=0}^{\tau-1} \mathbb{E} [w_m p_m(\delta + k + T_{m,1})], \quad (61)$$

and the threshold $\beta_{m,b}(\lambda)$ is the unique root of

$$\begin{aligned} & \mathbb{E} \left[\sum_{t=D_{m,i}(\beta_{m,b}(\lambda))}^{D_{m,i+1}(\beta_{m,b}(\lambda))-1} w_m p_m(\Delta_m(t)) \right] + \lambda \mathbb{E}[T_{m,i}] \\ & - \beta_{m,b}(\lambda) \mathbb{E} [D_{m,i+1}(\beta_{m,b}(\lambda)) - D_{m,i}(\beta_{m,b}(\lambda))] = 0. \quad (62) \end{aligned}$$

Furthermore, $\beta_{m,b}(\lambda)$ is equal to the optimal objective value to (59), i.e., $\beta_{m,b}(\lambda) = \bar{p}_{m,b,opt}(\lambda)$.

Proof. See Appendix M. \square

Now we present an optimal solution to (58).

Theorem 8. *If the conditions of Theorem 7 hold, then an optimal solution $(f_m^*(\lambda), g_m^*(\lambda))$ to (58) is determined by*

(a) $f_m^*(\lambda) = (b_m^*(\lambda), b_m^*(\lambda), \dots)$, where

$$b_m^*(\lambda) = \arg \min_{b \in \{0, 1, \dots, B_m - 1\}} \bar{p}_{m,b,opt}(\lambda), \quad (63)$$

and $\bar{p}_{m,b,opt}(\lambda)$ is the optimal objective value to (59).

(b) $g_m^*(\lambda) = (S_{m,1}^*(\lambda), S_{m,2}^*(\lambda), \dots)$, where

$$\begin{aligned} & S_{m,i+1}^*(\lambda) \\ &= \min_{t \in \mathbb{Z}} \{t \geq D_{m,i}^* : \gamma_m(\Delta_m(t)) \geq \bar{p}_{m,opt}(\lambda)\}, \quad (64) \end{aligned}$$

$D_{m,i}^(\lambda) = S_{m,i}^*(\lambda) + T_{m,i}$, $\gamma_m(\delta)$ is defined in (61), and $\bar{p}_{m,opt}(\lambda)$ is the optimal objective value of (58), given by*

$$\bar{p}_{m,opt}(\lambda) = \min_{b \in \{0, 1, \dots, B_m - 1\}} \bar{p}_{m,b,opt}(\lambda). \quad (65)$$

Proof. See Appendix M. \square

2) *Solution to (56)*: Next, we solve the dual problem (56). Let $c_{0,\lambda}^*(t) \in \{0, 1, \dots, N\}$ be the number of dummy bandits activated in time slot t in the optimal solution to (57) and let $c_{m,\lambda}^*(t) \in \{0, 1\}$ denote whether source m is under service in time slot t in the optimal solution to (58). The dual problem (56) is solved by the following stochastic sub-gradient algorithm:

$$\lambda_{k+1} = \lambda_k + \frac{\alpha}{k} \left\{ \frac{1}{T} \sum_{m=0}^M \sum_{t=0}^{T-1} c_{m,\lambda_k}^*(t) - N \right\}, \quad (66)$$

where $\alpha/k > 0$ is the step size and $T > 1$ is a sufficient large integer. In the k -th iteration, let $\lambda = \lambda_k$ and run the optimal solution to (55) for T time slots, then execute the dual update (66).

E. A Scheduling Policy for the Original Problem (44)-(46)

Now, we develop a scheduling policy for the original multi-action RMAB problem (44)-(46). The proposed policy contains two parts: (i) a Whittle index policy is used to determine which sources to schedule, and (ii) a λ^* -based selection-from-buffer policy is employed to determine which features to choose from the buffers of the scheduled sources.

1) *Whittle Index-based Source Scheduling Policy*: The Whittle index theory only applies to RMAB problems that are indexable [29]. Hence, we first establish the indexability of problem (47)-(50). Define $\Omega_m(\lambda)$ as the set of all states (δ, d) such that if $\Delta_m(t) = \delta$ and $d_m(t) = d$, then the optimal solution for (58) is to take the passive action at time t .

Definition 3 (Indexability). [17] *Bandit m is said to be indexable if, as the cost λ increases from $-\infty$ to ∞ , the set $\Omega_m(\lambda)$ increases monotonically, i.e., $\lambda_1 \leq \lambda_2$ implies $\Omega_m(\lambda_1) \subseteq \Omega_m(\lambda_2)$. The RMAB problem (47)-(50) is said to be indexable if all $(M+1)$ bandits are indexable.*

Theorem 9. *The RMAB problem (47)-(50) is indexable.*

Proof. See Appendix N. \square

Definition 4 (Whittle index). [17] *Given indexability, the Whittle index $W_m(\delta, d)$ of bandit m at state (δ, d) is*

$$W_m(\delta, d) = \inf\{\lambda \in \mathbb{R} : (\delta, d) \in \Omega_m(\lambda)\}. \quad (67)$$

Lemma 5. *The Whittle index of the dummy bandits is 0, i.e., $W_0(\delta, 0) = 0$ for any δ .*

Theorem 10. *The following assertions are true for the Whittle index $W_m(\delta, d)$ of bandit m for $m = 1, 2, \dots, M$:*

(a) *If $d = 0$, then for $m = 1, \dots, M$,*

$$W_m(\delta, 0) = \max_{b \in \mathbb{Z}: 0 \leq b \leq B_m - 1} W_{m,b}(\delta, 0), \quad (68)$$

where

$$W_{m,b}(\delta, 0) = \frac{1}{\mathbb{E}[T_{l,1}]} \mathbb{E} \left[D_{m,i+1}(\gamma_m(\delta)) - D_{m,i}(\gamma_m(\delta)) \right] \gamma_m(\delta) - \frac{1}{\mathbb{E}[T_{l,1}]} \mathbb{E} \left[\sum_{t=D_{m,i}(\gamma_m(\delta))}^{D_{m,i+1}(\gamma_m(\delta))-1} w_m p_m(\Delta_m(t)) \right], \quad (69)$$

$\Delta_m(t) = t - S_{m,i}(\gamma_m(\delta)) + b$, $\gamma_m(\delta)$ is defined in (61), $D_{m,i+1}(\gamma_m(\delta)) = S_{m,i+1}(\gamma_m(\delta)) + T_{m,i}$, and $S_{m,i+1}(\gamma_m(\delta))$ is given by

$$S_{m,i+1}(\gamma_m(\delta)) = \min_{t \in \mathbb{Z}} \{t \geq D_{m,i}(\gamma_m(\delta)) : \gamma_m(\Delta_m(t)) \geq \gamma_m(\delta)\}. \quad (70)$$

(b) *If $d > 0$, then $W_m(\delta, d) = -\infty$ for $m = 1, \dots, M$.*

Proof. See Appendix O. \square

Theorem 10 presents an analytical expression of the Whittle index of bandit m for $m = 1, 2, \dots, M$. If no feature of source m is being served by a channel at time slot t such that $d_m(t) = 0$, then the Whittle index of bandit m at time slot t is determined by (68). Otherwise, if source m is being

Algorithm 1 Scheduling Policy for Multi-source, Multi-channel Inference Error Minimization (44)-(46)

```

1: Initialize  $t = 0$ 
2: Input the optimal dual variable  $\lambda^*$  of the problem (56).
3: for  $t = 0, 1, \dots$  do
4:   Update  $\Delta_m(t)$  and  $d_m(t)$  for all  $m$ .
5:    $W_m \leftarrow W_m(\Delta_m(t), d_m(t))$  for all  $m$ .
6:   for all channel  $n = 1, 2, \dots, N$  do
7:     if channel  $n$  is idle and  $\max_l W_l > 0$  then
8:       Schedule source  $m = \arg \max_l W_l$ .
9:       Send the feature from the position  $b_m^*(\lambda^*)$  in
10:      source  $m$ 's buffer.
11:       $W_m \leftarrow -\infty$ .
12:     end if
13:   end for
14:    $t \leftarrow t + 1$ .
15: end for

```

served by a channel at time slot t such that $d_m(t) > 0$, then the Whittle index of bandit m at time t is $-\infty$.

In the special case that (i) the AoI function $p_m(\cdot)$ is non-decreasing and (ii) $T_{m,i} = 1$, it holds that $\gamma_m(\delta) = w_m p_m(\delta + 1)$ and for $\delta = 1, 2, \dots$,

$$W_m(\delta, 0) = w_m \left[\delta p_m(\delta + 1) - \sum_{k=1}^{\delta} p_m(k) \right]. \quad (71)$$

By this, the Whittle index in Section IV of [10, Equation (7)] is recovered from Theorem 10.

Let $A(t)$ denote the number of available channel at the beginning of time slot t , where $A(t) \leq N$. Then, $A(t)$ bandits with the highest Whittle index are activated at any time slot t . As stated in Lemma 5, all N dummy bandits have Whittle index of $W_0(\Delta_0(t), d_0(t)) = 0$. Consequently, if a bandit m (for $m = 1, 2, \dots, M$) possesses a negative Whittle index, denoted as $W_m(\Delta_m(t), d_m(t)) < 0$, it will remain inactive.

Now, we return to the original RMAB (44)-(46) with no dummy bandits. As illustrated in Algorithm 1, if channel n is idle, then source m with highest non-negative Whittle index is activated.

2) *λ^* -based Selection-from-Buffer Policy*: When the m -th bandit is activated, our policy in Algorithm 1 sends the feature from the buffer position $b_m^*(\lambda^*)$, determined by

$$b_m^*(\lambda^*) = \arg \min_{b \in \{0, 1, \dots, B_m - 1\}} \bar{p}_{m,b,opt}(\lambda^*), \quad (72)$$

where λ^* is the optimal solution to (56) and $\bar{p}_{m,b,opt}(\lambda)$ is the optimal objective value of (59).

F. Asymptotic Optimality of the Proposed Scheduling Policy

Let π_{our} denote the scheduling policy outlined in Algorithm 1. Now, we demonstrate that π_{our} is asymptotically optimal.

Definition 5 (Asymptotically optimal). [17], [18] *Initially, we have N channels and M sources. Let \bar{p}_π^r represent the expected long-term average inference error under policy π , where both the number of channels rN and the number of bandits rM are scaled by r . The policy π_{our} will be*

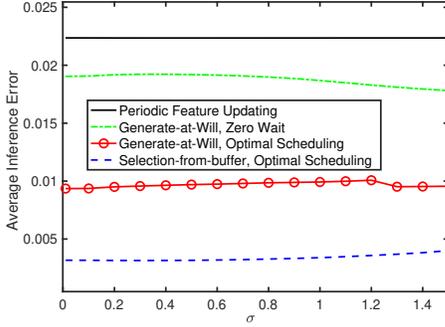

Fig. 9: Time average inference error vs. the scale parameter σ of discretized i.i.d. log-normal transmission time distribution for single-source scheduling (in robot state prediction task).

asymptotically optimal if $\bar{p}_{\pi_{\text{our}}}^r \leq \bar{p}_{\pi}^r$ for all $\pi \in \Pi$ as r approaches ∞ , while maintaining a constant ratio $\alpha = \frac{rM}{rN}$.

Theorem 11. If the feature transmission times $T_{m,i}$ are bounded for all m and i , then under the uniform global attractor condition provided in Appendix R, π_{our} is asymptotically optimal.

Proof sketch. We first establish that if m -th source is selected, then there exists an optimal feature selection policy that always selects features from the buffer position $b_m^*(\lambda^*)$. Hence, the multiple action RMAB problem (44)-(46) reduces to a binary action RMAB problem. Then, we use [18, Theorem 13] to prove Theorem 11. See Appendix R for details. \square

VII. DATA DRIVEN EVALUATIONS

In this section, we illustrate the performance of our scheduling policies, where we plug in the inference error versus AoI cost functions from the data driven experiments in Section II-C. Then, we simulate the performance of different scheduling policies.

A. Single-source Scheduling Policies

We evaluate the following four scheduling policies:

1. Generate-at-will, zero wait: The $(i+1)$ -th feature sending time S_{i+1} is given by $S_{i+1} = D_i = S_i + T_i$ and the feature selection policy is $f = (0, 0, \dots)$, i.e., $b_i = 0$ for all i .
2. Generate-at-will, optimal scheduling: The policy is given by Theorem 4 with $b_i = 0$ for all i .
3. Selection-from-buffer, optimal scheduling: The policy is given by Theorem 5.
4. Periodic feature updating: Features are generated periodically with a period T_p and appended to a queue with buffer size B . When the buffer is full, no new feature is admitted to the buffer. Features in the buffer are sent over the channel in a first-come, first-served order.

Figs. 9-10 compare the time-averaged inference error of the four single-source scheduling policies defined earlier. These policies are evaluated using the inference error function, $p(\delta)$, obtained from the robot state prediction experiment of the

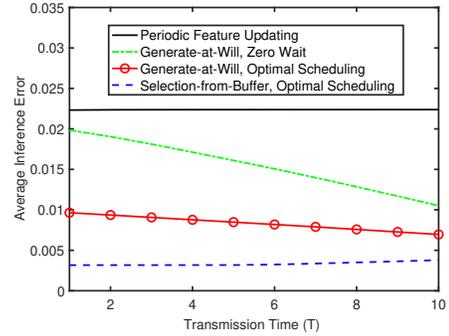

Fig. 10: Time-average inference error vs. constant transmission time T (in robot state prediction task).

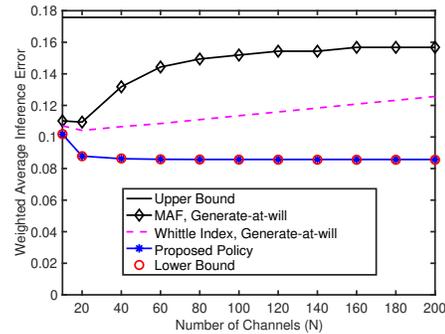

Fig. 11: Time-average weighted inference error vs. number of channels N .

leader-follower robotic system presented in Section II-C and illustrated in Fig. 2(c). The feature sequence length for this experiment is $u = 1$.

In Fig. 9, the i -th feature transmission time T_i is assumed to follow a discrete valued i.i.d. log-normal distribution. In particular, T_i can be expressed as $T_i = \lceil \alpha e^{\sigma Z_i} / \mathbb{E}[e^{\sigma Z_i}] \rceil$, where Z_i 's are i.i.d. Gaussian random variables with zero mean and unit variance. In Fig. 9, we plot the time average inference error versus the scale parameter σ of discretized i.i.d. log-normal distribution, where $\alpha = 1.2$, the buffer size is $B = 30$, and the period of uniform sampling is $T_p = 3$. The randomness of the transmission time increases with the growth of σ . Data-driven evaluations in Fig. 9 show that “selection-from-buffer” with optimal scheduler achieves 3 times performance gain compared to “generate-at-will,” and 8 times performance gain compared to periodic feature updating.

In Fig. 10, the time average inference error versus constant transmission time T . This figure also shows that “selection-from-buffer” with optimal scheduler can achieve 8 time performance gain compared to periodic feature updating.

B. Multiple-source Scheduling Policies

Now, we evaluate the following three multiple-source scheduling policies:

1. Maximum age first (MAF), Generate-at-will: At time slot t , if a channel is free, this policy schedules the freshest generated feature from source $\arg \max_{l \in A(t)} \Delta_l(t)$, where $A(t)$ is the set of available sources in time slot t .

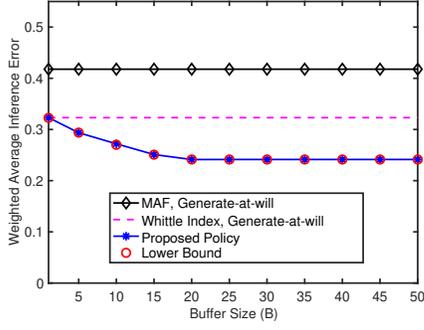

Fig. 12: Weighted time-average inference error vs. buffer size (B).

2. Whittle index, Generate-at-will: Denote

$$l_0^* = \arg \max_{l \in A(t)} W_{l,0}(\Delta_l(t)). \quad (73)$$

If a channel is free and $\max_{l \in A(t)} W_{l,0}(\Delta_l(t)) \geq 0$, the freshest feature from the source l_0^* is scheduled; otherwise, no source is scheduled.

3. Proposed Policy: The policy is described in Algorithm 1.
4. Lower bound: Given the optimal dual variable $\lambda = \lambda^*$, the lower bound is obtained by implementing policy $(f_m^*(\lambda^*), g_m^*(\lambda^*))_{m=0}^M$, which is defined in Theorem 8.
5. Upper bound: The upper bound is obtained if none of the sources is scheduled at every time slot t .

Figs. 11-12 compare our proposed policy with others under a multi-source scenario with $m = 500$ sources. The inference error for half the sources (weight $w_1 = 1$, feature sequence length $u = 5$) originates from the pole angle prediction of the CartPole-v1 task in Sec. II-C (Fig. 3(c)). The remaining sources (weight $w_2 = 5$, feature sequence length $u = 1$) use inference error from the robot state prediction experiment of the leader-follower robotic system presented in Sec. II-C (Fig. 2(c)). Notably, the transmission time for all features is considered constant at 1.

In Fig. 11, we plot the weighted time-average inference error versus the number of channels, where the buffer size of all sources is set to 40 (i.e., $B_l = B = 40$ for all l). From Fig. 11, it is evident that our proposed policy outperforms the “Whittle index, Generate-at-will” and “MAF, Generate-at-will” policies. Specifically, our policy achieves a weighted average inference error that is twice as low as that of the “MAF, Generate-at-will” policy. Furthermore, as shown in Fig. 11, the performance of our policy matches the lower bound of the multi-source, multi-action scheduling problem, thereby validating its asymptotic optimality.

Fig. 12 illustrates the weighted time-average inference error versus the buffer size B , with the number of channels set to $N = 50$. The results presented in Fig. 12 underscore the effectiveness of the “selection-from-buffer” model. The weighted time-average inference error achieved by our policy decreases as the buffer size B increases, eventually reaching a plateau at a buffer size of 20.

VIII. CONCLUSIONS

In this paper, we explored the impact of data freshness on the performance of remote inference systems. Our analysis

revealed that the inference error in a remote inference system is a function of AoI, but not necessarily a monotonic function of AoI. If the target and feature data sequence satisfy a Markov chain, then the inference error is a monotonic function of AoI. Otherwise, if the target and feature data sequence is far from a Markov chain, then the inference error can be a non-monotonic function of AoI. To reduce the time-average inference error, we introduced a new feature transmission model called “selection-from-buffer” and designed an optimal single-source scheduling policy. The optimal single-source scheduling policy is found to be a threshold policy. Additionally, we developed a new asymptotically optimal policy for multi-source scheduling. Our numerical results validated the efficacy of the proposed scheduling policies.

ACKNOWLEDGEMENT

The authors are grateful to Vijay Subramanian for one suggestion, to John Hung for useful discussions on this work, and to Shaoyi Li for his help on Fig. 1(b)-(c).

APPENDIX A

DETAILED SETTINGS OF EXPERIMENTS IN SEC. II-C

In all five experiments, we employed the first training method described in Section II-B. This approach involves training multiple neural networks independently and in parallel, each using a distinct dataset with a different AoI value. In contrast, the second approach trains a single neural network on a larger, combined dataset encompassing various AoI values. Due to the smaller dataset sizes for each network, the first approach can potentially have a shorter training time than the second approach. The experimental settings of the five experiments are provided below:

A. Video Prediction

In video prediction experiment, a pre-trained neural network model called ‘‘SAVP’’ [19] is used to evaluate on 256 samples of ‘‘BAIR’’ dataset [53], which contains video frames of a randomly moving robotic arm. The pre-trained neural network model can be downloaded from the GitHub repository of [19].

B. Robot State Prediction

In this experiment, we consider a leader-follower robotic system illustrated in a YouTube video ⁴, where we used two Kinova JACO robotic arms with 7 degrees of freedom and 3 fingers to accomplish a pick and place task. The leader robot sends its state (7 joint angles and positions of 3 fingers) X_t to the follower robot through a channel. One packet for updating the leader robot’s state is sent periodically to the follower robot every 20 time-slots. The transmission time of each updating packet is 20 time-slots. The follower robot moves towards the leader’s most recent state and locally controls its robotic fingers to grab an object. We constructed a robot simulation environment using the Robotics System Toolbox in MATLAB. In each episode, a can is randomly generated on a table in front of the follower robot. The leader robot observes the position of the can and illustrates to the follower robot how to grab the can and place it on another table, without colliding with other objects in the environment. The rapidly-exploring random tree (RRT) algorithm is used to control the leader robot [54]. For the local control of the follower robot, an interpolation method is used to generate a trajectory between two points sent from the leader robot while also avoiding collisions with other obstacles. The leader robot uses a neural network to predict the follower robot’s state Y_t . The neural network consists of one input layer, one hidden layer with 256 ReLU activation nodes, and one fully connected (dense) output layer. The dataset contains the leader and follower robots’ states in 300 episodes of continue operation. The first 80% of the dataset is used for the training and the other 20% of the dataset is used for the inference.

C. Actuator State Prediction

We consider the OpenAI CartPole-v1 task [33], where a DQN reinforcement learning algorithm [55] is used to control

the force on a cart and keep the pole attached to the cart from falling over. By simulating 10^4 episodes of the OpenAI CartPole-v1 environment, a time-series dataset is collected that contains the pole angle ψ_t and the velocity v_t of the cart. The pole angle ψ_t at time t is predicted based on a feature $X_{t-\delta} = (v_{t-\delta}, \dots, v_{t-\delta-u+1})$, i.e., a vector of cart velocity with length u , where v_t is the cart velocity at time t and $\Delta(t) = \delta$ is the AoI. The predictor in this experiment is an LSTM neural network that consists of one input layer, one hidden layer with 64 LSTM cells, and a fully connected output layer. First 72% of the dataset is used for training and the rest of the dataset is used for inference.

D. Temperature prediction

The temperature Y_t at time t is predicted based on a feature $X_{t-\delta} = \{s_{t-\delta}, \dots, s_{t-\delta-u+1}\}$, where s_t is a 7-dimensional vector consisting of temperature, pressure, saturation vapor pressure, vapor pressure deficit, specific humidity, airtightness, and wind speed at time t . We used the Jena climate dataset recorded by the Max Planck Institute for Biogeochemistry [56]. The dataset comprises 14 features, including temperature, pressure, humidity, etc., recorded once every 10 minutes from 10 January 2009 to 31 December 2016. The first 75% of the dataset is used for training and the later 25% is used for inference. Temperature is predicted every hour using an LSTM neural network composed of one input layer, one hidden layer with 32 LSTM units, and one output layer.

E. CSI Prediction

The CSI h_t at time t is predicted based on a feature $X_{t-\delta} = \{h_{t-\delta}, \dots, h_{t-\delta-u+1}\}$. The dataset for CSI is generated by using Jakes model [57].

APPENDIX B

EXAMPLES OF LOSS FUNCTION L , L -ENTROPY, AND L -CROSS ENTROPY

Several examples of loss function L , L -entropy, and L -cross entropy are listed below. Additional examples can be found in [34]–[36].

1) *Logarithmic Loss (log-loss)*: The log-loss function is given by $L_{\log}(y, Q_Y) = -\log Q_Y(y)$, where the action $a = Q_Y$ is a distribution in $\mathcal{P}^{\mathcal{Y}}$. The corresponding L -entropy is the well-known Shannon’s entropy [42], defined as

$$H_{\log}(Y) = - \sum_{y \in \mathcal{Y}} P_Y(y) \log P_Y(y), \quad (74)$$

where P_Y is the distribution of Y . The corresponding L -cross entropy is given by

$$H_{\log}(Y; \tilde{Y}) = - \sum_{y \in \mathcal{Y}} P_Y(y) \log P_{\tilde{Y}}(y). \quad (75)$$

The L -mutual information and L -divergence associated with the log-loss are Shannon’s mutual information and the K-L divergence defined in (17), respectively.

⁴https://youtu.be/_z4FHuu3-ag

2) *Brier Loss*: The Brier loss function is defined as $L_B(y, Q_Y) = \sum_{y' \in \mathcal{Y}} Q_Y(y')^2 - 2 Q_Y(y) + 1$ [34]. The associated L -entropy is given by

$$H_B(Y) = 1 - \sum_{y \in \mathcal{Y}} P_Y(y)^2, \quad (76)$$

and the associated L -cross entropy is

$$H_B(Y; \tilde{Y}) = \sum_{y \in \mathcal{Y}} P_{\tilde{Y}}(y)^2 - 2 \sum_{y \in \mathcal{Y}} P_{\tilde{Y}}(y) P_Y(y) + 1. \quad (77)$$

3) *0-1 Loss*: The 0-1 loss function is given by $L_{0-1}(y, \hat{y}) = \mathbf{1}(y \neq \hat{y})$, where $\mathbf{1}(A)$ is the indicator function of event A . For this case, we have

$$H_{0-1}(Y) = 1 - \max_{y \in \mathcal{Y}} P_Y(y), \quad (78)$$

$$H_{0-1}(Y; \tilde{Y}) = 1 - P_Y \left(\arg \max_{y \in \mathcal{Y}} P_{\tilde{Y}}(y) \right). \quad (79)$$

4) α -Loss: The α -loss function is defined by $L_\alpha(y, Q_Y) = \frac{\alpha}{\alpha-1} \left[1 - Q_Y(y)^{\frac{\alpha-1}{\alpha}} \right]$ for $\alpha > 0$ and $\alpha \neq 1$ [58, Eq. 14]. It becomes the log-loss function in the limit $\alpha \rightarrow 1$ and the 0-1 loss function in the limit $\alpha \rightarrow \infty$. The L -entropy and L -cross entropy associated with the α -loss function are given by

$$H_{\alpha\text{-loss}}(Y) = \frac{\alpha}{\alpha-1} \left[1 - \left(\sum_{y \in \mathcal{Y}} P_Y(y)^\alpha \right)^{\frac{1}{\alpha}} \right], \quad (80)$$

$$H_{\alpha\text{-loss}}(Y; \tilde{Y}) = \frac{\alpha}{\alpha-1} \left[1 - \left(\sum_{y \in \mathcal{Y}} P_{\tilde{Y}}(y)^\alpha \right)^{\frac{1}{\alpha}} \right] \lambda, \quad (81)$$

where

$$\lambda = \frac{\sum_{y \in \mathcal{Y}} \frac{P_Y(y)}{P_{\tilde{Y}}(y)} P_{\tilde{Y}}(y)^\alpha}{\sum_{y \in \mathcal{Y}} P_{\tilde{Y}}(y)^\alpha}. \quad (82)$$

5) *Quadratic Loss*: The quadratic loss function is $L_2(y, \hat{y}) = (y - \hat{y})^2$. The L -entropy function associated with the quadratic loss is the variance of Y , given by

$$H_2(Y) = \mathbb{E}[Y^2] - \mathbb{E}[Y]^2. \quad (83)$$

The corresponding L -cross entropy is

$$H_2(Y; \tilde{Y}) = \mathbb{E}[Y^2] - 2\mathbb{E}[\tilde{Y}]\mathbb{E}[Y] + \mathbb{E}[\tilde{Y}]^2. \quad (84)$$

APPENDIX C

DEFINITIONS OF L -DIVERGENCE, L -MUTUAL INFORMATION, AND L -CONDITIONAL MUTUAL INFORMATION

The L -divergence $D_L(P_Y || P_{\tilde{Y}})$ of P_Y from $P_{\tilde{Y}}$ can be expressed as [34], [36]

$$\begin{aligned} D_L(P_Y || P_{\tilde{Y}}) &= \mathbb{E}_{Y \sim P_Y} [L(Y, a_{P_Y})] - \mathbb{E}_{Y \sim P_Y} [L(Y, a_{P_{\tilde{Y}}})]. \end{aligned} \quad (85)$$

Because a_{P_Y} is an optimal to (7), from (85), we have

$$D_L(P_Y || P_{\tilde{Y}}) \geq 0. \quad (86)$$

The L -mutual information $I_L(Y; X)$ is defined as [34], [36]

$$\begin{aligned} I_L(Y; X) &= \mathbb{E}_{X \sim P_X} [D_L(P_{Y|X} || P_Y)] \\ &= H_L(Y) - H_L(Y|X) \geq 0, \end{aligned} \quad (87)$$

which measures the performance gain in predicting Y by observing X . In general, $I_L(X; Y) \neq I_L(Y; X)$. The L -conditional mutual information $I_L(Y; X|Z)$ is given by

$$\begin{aligned} I_L(Y; X|Z) &= \mathbb{E}_{X, Z \sim P_{X, Z}} [D_L(P_{Y|X, Z} || P_{Y|Z})] \\ &= H_L(Y|Z) - H_L(Y|X, Z) \geq 0. \end{aligned} \quad (88)$$

APPENDIX D

RELATIONSHIP AMONG L -DIVERGENCE, BREGMAN DIVERGENCE, AND f -DIVERGENCE

We explain the relationship among the L -divergence defined in (85), the Bregman divergence [59], and the f -divergence [39]. All these three classes of divergence have been widely used in the machine learning literature. Their differences are explained below.

Let $\mathcal{P}^{\mathcal{Y}}$ denote the set of all probability distributions on the discrete set \mathcal{Y} . Define $\mathcal{Z} \subset \mathbb{R}^{|\mathcal{Y}|}$ as the set of all probability vectors $\mathbf{z} = (z_1, \dots, z_{|\mathcal{Y}|})^T$ that satisfy $\sum_{i=1}^{|\mathcal{Y}|} z_i = 1$ and $z_i \geq 0$ for all $i = 1, 2, \dots, |\mathcal{Y}|$. Any distribution $P_Y \in \mathcal{P}^{\mathcal{Y}}$ can be represented by a probability vector $\mathbf{p}_Y = (P_Y(y_1), \dots, P_Y(y_{|\mathcal{Y}|}))^T \in \mathcal{Z}$.

Definition 6. [59] Let $F : \mathcal{Z} \mapsto \mathbb{R}$ be a continuously differentiable and strictly convex function defined on the convex set \mathcal{Z} . The Bregman divergence associated with F between two distributions $P_Y, Q_Y \in \mathcal{P}^{\mathcal{Y}}$ is defined as

$$B_F(P_Y || Q_Y) = F(\mathbf{p}_Y) - F(\mathbf{q}_Y) - \nabla F(\mathbf{q}_Y)^T (\mathbf{p}_Y - \mathbf{q}_Y), \quad (89)$$

where $\mathbf{p}_Y \in \mathcal{Z}$ and $\mathbf{q}_Y \in \mathcal{Z}$ are two probability vectors associated with the distributions P_Y and Q_Y , respectively, and $\nabla F = \left(\frac{\partial F}{\partial z_1}, \dots, \frac{\partial F}{\partial z_{|\mathcal{Y}|}} \right)^T$.

We establish the following lemma:

Lemma 6. For any continuously differentiable and strictly convex function $F : \mathcal{Z} \mapsto \mathbb{R}$, the Bregman divergence $B_F(P_Y || Q_Y)$ associated with F is an L_F -divergence $D_{L_F}(P_Y || Q_Y)$ associated with the loss function

$$L_F(y, Q_Y) = -F(\mathbf{q}_Y) - \frac{\partial F(\mathbf{q}_Y)}{\partial z_y} + \nabla F(\mathbf{q}_Y)^T \mathbf{q}_Y. \quad (90)$$

Proof. According to (7), the L_F -entropy associated with the loss function $L_F(y, Q_Y)$ in (90) is defined as

$$H_{L_F}(Y) = \min_{Q_Y \in \mathcal{P}^{\mathcal{Y}}} \mathbb{E}_{Y \sim P_Y} [L_F(Y, Q_Y)], \quad (91)$$

where P_Y is the distribution of Y . Using (90), we can get

$$\begin{aligned} & \mathbb{E}_{Y \sim P_Y} [L_F(Y, Q_Y)] \\ &= - \sum_{y \in \mathcal{Y}} P_Y(y) F(\mathbf{q}_Y) - \sum_{y \in \mathcal{Y}} P_Y(y) \frac{\partial F(\mathbf{q}_Y)}{\partial z_y} \\ & \quad + \sum_{y \in \mathcal{Y}} P_Y(y) \nabla F(\mathbf{q}_Y)^T \mathbf{q}_Y \\ &= -F(\mathbf{q}_Y) - \nabla F(\mathbf{q}_Y)^T (\mathbf{p}_Y - \mathbf{q}_Y), \end{aligned} \quad (92)$$

where the last equality holds because $F(\mathbf{q}_Y)$ and $\nabla F(\mathbf{q}_Y)^T \mathbf{q}_Y$ are constants that remain unchanged regardless of the variable y . Because the function F is continuously differentiable and strictly convex on the convex set \mathcal{Z} , we have for all $\mathbf{p}_Y, \mathbf{q}_Y \in \mathcal{Z}$

$$-F(\mathbf{q}_Y) - \nabla F(\mathbf{q}_Y)^T (\mathbf{p}_Y - \mathbf{q}_Y) \geq -F(\mathbf{p}_Y). \quad (93)$$

Equality holds in (93) if and only if $\mathbf{q}_Y = \mathbf{p}_Y$. From (91), (92), and (93), we obtain

$$\begin{aligned} H_{L_F}(Y) &= \min_{\mathbf{q}_Y \in \mathcal{Z}} -F(\mathbf{q}_Y) - \nabla F(\mathbf{q}_Y)^T (\mathbf{p}_Y - \mathbf{q}_Y) \\ &= -F(\mathbf{p}_Y). \end{aligned} \quad (94)$$

Substituting (92) and (94) into (89), yields

$$\begin{aligned} &B_F(P_Y \| Q_Y) \\ &= F(\mathbf{p}_Y) - F(\mathbf{q}_Y) - \nabla F(\mathbf{q}_Y)^T (\mathbf{p}_Y - \mathbf{q}_Y) \\ &= E_{Y \sim P_Y} [L_F(Y, Q_Y)] - H_{L_F}(Y) \\ &= D_{L_F}(P_Y \| Q_Y). \end{aligned} \quad (95)$$

This completes the proof. \square

Let us rewrite the L -entropy $H_L(Y)$ as $H_L(\mathbf{p}_Y)$ to emphasize that it is a function of the probability vector \mathbf{p}_Y . If $H_L(\mathbf{p}_Y)$ is continuously differentiable and strictly concave in \mathbf{p}_Y , then the L -divergence $D_L(P_Y \| Q_Y)$ can be expressed as [34, Section 3.5.4]

$$\begin{aligned} &D_L(P_Y \| Q_Y) \\ &= H_L(\mathbf{q}_Y) + \nabla H_L(\mathbf{q}_Y)^T (\mathbf{p}_Y - \mathbf{q}_Y) - H_L(\mathbf{p}_Y) \\ &= B_{-H_L}(P_Y \| Q_Y), \end{aligned} \quad (96)$$

which is the Bregman divergence $B_{-H_L}(P_Y \| Q_Y)$ associated with the continuously differentiable and strictly convex $-H_L$. However, if $H_L(\mathbf{p}_Y)$ is not continuously differentiable or not strictly concave in \mathbf{p}_Y , $D_L(P_Y \| Q_Y)$ is not necessarily a Bregman divergence.

Definition 7. [39] Let $f : (0, \infty) \mapsto \mathbb{R}$ be a convex function with $f(1) = 0$. The f -divergence between two probability distributions $P_Y, Q_Y \in \mathcal{P}^{\mathcal{Y}}$ is defined as

$$D_f(P_Y \| Q_Y) = \sum_{y \in \mathcal{Y}} Q_Y(y) f\left(\frac{P_Y(y)}{Q_Y(y)}\right). \quad (97)$$

An f -divergence may not be L -divergence, and vice versa. In fact, the KL divergence $D_{\log}(P_Y \| Q_Y)$ defined in (17) and its dual $D_{\log}(Q_Y \| P_Y)$ are the unique divergences belonging to both the classes of f -divergence and Bregman divergence [60]. Because KL divergence is also an L -divergence, $D_{\log}(P_Y \| Q_Y)$ and $D_{\log}(Q_Y \| P_Y)$ are the only divergences belonging to all the three classes of divergences.

The f -mutual information can be expressed using the f -divergence as

$$I_f(Y; X) = \mathbb{E}_{X \sim P_X} [D_f(P_{Y|X} \| P_Y)]. \quad (98)$$

The f -mutual information is symmetric, i.e., $I_f(Y; X) = I_f(X; Y)$, which can be shown as follows:

$$\begin{aligned} I_f(Y; X) &= \sum_{x \in \mathcal{X}} P_X(x) \sum_{y \in \mathcal{Y}} P_Y(y) f\left(\frac{P_{Y|X}(y|x)}{P_Y(y)}\right) \\ &= \sum_{\substack{x \in \mathcal{X} \\ y \in \mathcal{Y}}} P_X(x) P_Y(y) f\left(\frac{P_{Y|X}(y|x) P_X(x)}{P_Y(y) P_X(x)}\right) \\ &= \sum_{\substack{x \in \mathcal{X} \\ y \in \mathcal{Y}}} P_X(x) P_Y(y) f\left(\frac{P_{X|Y}(x|y) P_Y(y)}{P_Y(y) P_X(x)}\right) \\ &= \sum_{y \in \mathcal{Y}} P_Y(y) \sum_{x \in \mathcal{X}} P_X(x) f\left(\frac{P_{X|Y}(x|y)}{P_X(x)}\right) \\ &= I_f(X; Y). \end{aligned} \quad (99)$$

On the other hand, the L -mutual information is generally non-symmetric, i.e., $I_L(Y; X) \neq I_L(X; Y)$, except for some special cases. For example, Shannon's mutual information is defined by

$$I_{\log}(Y; X) = \mathbb{E}_{X \sim P_X} [D_{\log}(P_{Y|X} \| P_Y)], \quad (100)$$

which is both an L -mutual information and a f -mutual information. It is well-known that $I_{\log}(Y; X) = I_{\log}(X; Y)$.

APPENDIX E PROOF OF EQUATION (4)

Because we assume that Y_t and $X_{t-\delta}$ are independent of $\Delta(t)$, for all $y \in \mathcal{Y}$, $x \in \mathcal{X}$, and $\delta \in \mathbb{Z}^+$, we have

$$P_{Y_t, X_{t-\delta} | \Delta(t)=\delta}(y, x) = P_{Y_t, X_{t-\delta}}(y, x). \quad (101)$$

By using ϕ^* on the inference dataset, the inference error given $\Delta(t) = \delta$ is determined by

$$p(\delta) = \mathbb{E}_{Y, X \sim P_{Y_t, X_{t-\delta} | \Delta(t)=\delta}} [L(Y, \phi^*(X, \delta))], \quad (102)$$

where $P_{Y_t, X_{t-\delta} | \Delta(t)=\delta}$ is the distribution of target Y_t and feature $X_{t-\delta}$ given $\Delta(t) = \delta$.

By substituting (101) into (102), we obtain

$$\begin{aligned} p(\delta) &= \mathbb{E}_{Y, X \sim P_{Y_t, X_{t-\delta} | \Delta(t)=\delta}} [L(Y, \phi^*(X, \delta))] \\ &= \mathbb{E}_{Y, X \sim P_{Y_t, X_{t-\delta} | \Delta(t)=\delta}} [L(Y, \phi^*(X, \delta))] \\ &= \mathbb{E}_{Y, X \sim P_{Y_t, X_{t-\delta}}} [L(Y, \phi^*(X, \delta))] \\ &= \mathbb{E}_{Y, X \sim P_{Y_\delta, X_0}} [L(Y, \phi^*(X, \delta))]. \end{aligned} \quad (103)$$

The last equality holds due to the stationarity of $\{(Y_t, X_t), t = 0, 1, 2, \dots\}$. This completes the proof. \square

APPENDIX F
PROOF OF EQUATION (12)

Let $\mathcal{D} = \{\delta : P_\Theta(\delta) > 0\}$ be support set of P_Θ . From (11), we have

$$\begin{aligned} & H_L(\tilde{Y}_0|\tilde{X}_{-\Theta}, \Theta) \\ &= \sum_{x \in \mathcal{X}, \delta \in \mathcal{D}} P_{\tilde{X}_{-\Theta}, \Theta}(x, \delta) H_L(\tilde{Y}_0|\tilde{X}_{-\Theta} = x, \Theta = \delta) \\ &= \sum_{\delta \in \mathcal{D}} P_\Theta(\delta) \sum_{x \in \mathcal{X}} P_{\tilde{X}_{-\Theta}|\Theta=\delta}(x) H_L(\tilde{Y}_0|\tilde{X}_{-\Theta} = x, \Theta = \delta) \\ &= \sum_{\delta \in \mathcal{D}} P_\Theta(\delta) \sum_{x \in \mathcal{X}} P_{\tilde{X}_{-\delta}|\Theta=\delta}(x) H_L(\tilde{Y}_0|\tilde{X}_{-\Theta} = x, \Theta = \delta). \end{aligned} \quad (104)$$

Next, from (8), we obtain that for all $x \in \mathcal{X}$ and $\delta \in \mathcal{D}$,

$$\begin{aligned} & H_L(\tilde{Y}_0|\tilde{X}_{-\Theta} = x, \Theta = \delta) \\ &= \min_{a \in \mathcal{A}} \mathbb{E}_{Y \sim P_{\tilde{Y}_0|\tilde{X}_{-\Theta}=x, \Theta=\delta}} [L(Y, a)] \\ &= \min_{a \in \mathcal{A}} \mathbb{E}_{Y \sim P_{\tilde{Y}_0|\tilde{X}_{-\delta}=x, \Theta=\delta}} [L(Y, a)]. \end{aligned} \quad (105)$$

Because we assume that \tilde{Y}_0 and \tilde{X}_{-k} are independent of Θ for every $k \geq 0$, for all $x \in \mathcal{X}$, $y \in \mathcal{Y}$ and $\delta \in \mathcal{D}$

$$P_{\tilde{Y}_0|\tilde{X}_{-\delta}=x, \Theta=\delta}(y) = P_{\tilde{Y}_0|\tilde{X}_{-\delta}=x}(y), \quad (106)$$

$$P_{\tilde{X}_{-\delta}|\Theta=\delta}(x) = P_{\tilde{X}_{-\delta}}(x). \quad (107)$$

Substituting (106) into (105), we get

$$\begin{aligned} & H_L(\tilde{Y}_0|\tilde{X}_{-\Theta} = x, \Theta = \delta) \\ &= \min_{a \in \mathcal{A}} \mathbb{E}_{Y \sim P_{\tilde{Y}_0|\tilde{X}_{-\delta}=x}} [L(Y, a)] \\ &= H_L(\tilde{Y}_0|\tilde{X}_{-\delta} = x). \end{aligned} \quad (108)$$

Substituting (108) and (107) into (104), we observe that

$$\begin{aligned} H_L(\tilde{Y}_0|\tilde{X}_{-\Theta}, \Theta) &= \sum_{\delta \in \mathcal{D}} P_\Theta(\delta) \sum_{x \in \mathcal{X}} P_{\tilde{X}_{-\delta}}(x) H_L(\tilde{Y}_0|\tilde{X}_{-\delta} = x) \\ &= \sum_{\delta \in \mathcal{Z}^+} P_\Theta(\delta) H_L(\tilde{Y}_0|\tilde{X}_{-\delta}). \end{aligned} \quad (109)$$

This completes the proof.

APPENDIX G
PROOF OF LEMMA 1

This is due to the following symmetry property:

$$I_{\log}(Y; Z|X) = I_{\log}(Z; Y|X). \quad (110)$$

APPENDIX H
PROOF OF LEMMA 2

By using the definition of L -conditional mutual information in (88), we obtain

$$\begin{aligned} H_L(Y|X, Z) &= H_L(Y|X) - I_L(Y; Z|X) \\ &= H_L(Y|Z) - I_L(Y; X|Z). \end{aligned} \quad (111)$$

From (88) and (111), we get

$$\begin{aligned} H_L(Y|X) &= H_L(Y|Z) + I_L(Y; Z|X) - I_L(Y; X|Z) \\ &\leq H_L(Y|Z) + I_L(Y; Z|X), \end{aligned} \quad (112)$$

where the last inequality is due to $I_L(Y; X|Z) \geq 0$. Now, we need to show that if $Y \stackrel{\epsilon}{\leftrightarrow} X \stackrel{\epsilon}{\leftrightarrow} Z$, then

$$I_L(Y; Z|X) = O(\epsilon). \quad (113)$$

and in addition, if $H_L(Y)$ is twice differentiable, then

$$I_L(Y; Z|X) = O(\epsilon^2). \quad (114)$$

From (88), we see that

$$I_L(Y; Z|X) = \mathbb{E}_{X, Z} [D_L(P_{Y|X, Z} || P_{Y|X})]. \quad (115)$$

We know from Pinsker's inequality [42, Lemma 11.6.1] that

$$\sum_{y \in \mathcal{Y}} (P_Y(y) - Q_Y(y))^2 \leq 2 \ln 2 D_{\log}(P_Y || Q_Y). \quad (116)$$

If $Y \stackrel{\epsilon}{\leftrightarrow} X \stackrel{\epsilon}{\leftrightarrow} Z$ is an ϵ -Markov chain, then Definition 1 yields:

$$\sum_{(x, z) \in \mathcal{X} \times \mathcal{Z}} P_{X, Z}(x, z) D_{\log}(P_{Y|X=x, Z=z} || P_{Y|X=x}) \leq \epsilon^2. \quad (117)$$

Let $\mathcal{X}' \times \mathcal{Z}' = \{(x, z) : P_{X, Z}(x, z) > 0\}$ be the support set of $P_{X, Z}$. Then, (118) reduces to

$$\sum_{(x, z) \in \mathcal{X}' \times \mathcal{Z}'} P_{X, Z}(x, z) D_{\log}(P_{Y|X=x, Z=z} || P_{Y|X=x}) \leq \epsilon^2. \quad (118)$$

Because the left side of the above inequality is the summation of non-negative terms, the following holds:

$$P_{X, Z}(x, z) D_{\log}(P_{Y|X=x, Z=z} || P_{Y|X=x}) \leq \epsilon^2, \quad (119)$$

for all $(x, z) \in \mathcal{X}' \times \mathcal{Z}'$. Because $P_{X, Z}(x, z) > 0$ for all $(x, z) \in \mathcal{X}' \times \mathcal{Z}'$, from (116) and (119), we can write

$$\sum_{y \in \mathcal{Y}} (P_{Y|X=x, Z=z}(y) - P_{Y|X=x}(y))^2 \leq \frac{2 \ln 2 \epsilon^2}{P_{X, Z}(x, z)}, \quad (120)$$

for all $(x, z) \in \mathcal{X}' \times \mathcal{Z}'$. Next, we need the following lemma.

Lemma 7. *The following assertions are true:*

(a) *If two distributions $Q_Y \in \mathcal{P}^{\mathcal{Y}}$ and $P_Y \in \mathcal{P}^{\mathcal{Y}}$ satisfy*

$$\sum_{y \in \mathcal{Y}} (P_Y(y) - Q_Y(y))^2 \leq \beta^2, \quad (121)$$

then

$$D_L(P_Y || Q_Y) = O(\beta). \quad (122)$$

(b) *If, in addition, $H_L(Y)$ is twice differentiable in P_Y , then*

$$D_L(P_Y || Q_Y) = O(\beta^2). \quad (123)$$

Proof. See in Appendix P. \square

Using (120) and Lemma 7(a) in (115), we obtain

$$\begin{aligned}
& I_L(Y; Z|X) \\
&= \sum_{(x,z) \in \mathcal{X} \times \mathcal{Z}} P_{X,Z}(x,z) D_L(P_{Y|X=x,Z=z} \| P_{Y|X=x}) \\
&= \sum_{(x,z) \in \mathcal{X}' \times \mathcal{Z}'} P_{X,Z}(x,z) D_L(P_{Y|X=x,Z=z} \| P_{Y|X=x}) \\
&= \sum_{(x,z) \in \mathcal{X}' \times \mathcal{Z}'} P_{X,Z}(x,z) O\left(\frac{\sqrt{2\ln 2}\epsilon}{\sqrt{P_{X,Z}(x,z)}}\right) \\
&= O(\epsilon). \tag{124}
\end{aligned}$$

Similarly, when $H_L(Y)$ is differentiable in P_Y , by using Lemma 7(b) we obtain

$$I_L(Y; Z|X) = O(\epsilon^2). \tag{125}$$

This completes the proof of Lemma 2.

APPENDIX I PROOF OF THEOREM 1

By using the definition of L -conditional mutual information in (88), we can show that

$$\begin{aligned}
& H_L(\tilde{Y}_0 | \tilde{X}_{-k}, \tilde{X}_{-k-1}) \\
&= H_L(\tilde{Y}_0 | \tilde{X}_{-k-1}) - I_L(\tilde{Y}_0; \tilde{X}_{-k} | \tilde{X}_{-k-1}) \\
&= H_L(\tilde{Y}_0 | \tilde{X}_{-k}) - I_L(\tilde{Y}_0; \tilde{X}_{-k-1} | \tilde{X}_{-k}). \tag{126}
\end{aligned}$$

Expanding $H_L(\tilde{Y}_0 | \tilde{X}_{-k})$, we have

$$\begin{aligned}
H_L(\tilde{Y}_0 | \tilde{X}_{-k}) &= H_L(\tilde{Y}_0 | \tilde{X}_{-k-1}) + I_L(\tilde{Y}_0; \tilde{X}_{-k-1} | \tilde{X}_{-k}) \\
&\quad - I_L(\tilde{Y}_0; \tilde{X}_{-k} | \tilde{X}_{-k-1}). \tag{127}
\end{aligned}$$

Since the above equation is valid for all values of $k \geq 0$, taking the summation of $H_L(\tilde{Y}_0 | \tilde{X}_{-k})$ from $k = 0$ to $\delta - 1$ yields:

$$\begin{aligned}
H_L(\tilde{Y}_0 | \tilde{X}_{-\delta}) &= H_L(\tilde{Y}_0 | \tilde{X}_0) + \sum_{k=0}^{\delta-1} I_L(\tilde{Y}_0; \tilde{X}_{-k} | \tilde{X}_{-k-1}) \\
&\quad - \sum_{k=0}^{\delta-1} I_L(\tilde{Y}_0; \tilde{X}_{-k-1} | \tilde{X}_{-k}). \tag{128}
\end{aligned}$$

Thus, we can express $H_L(\tilde{Y}_0 | \tilde{X}_{-\delta})$ as a function of δ as in (20) and (21). Moreover, the functions $g_1(\delta)$ and $g_2(\delta)$ defined in (21) are non-decreasing in δ as $I_L(\tilde{Y}_0; \tilde{X}_{-k} | \tilde{X}_{-k-1}) \geq 0$ and $I_L(\tilde{Y}_0; \tilde{X}_{-k-1} | \tilde{X}_{-k}) \geq 0$ for all values of k .

To prove the next part, we use Lemma 2. Because for every $\mu, \nu \geq 0$, $\tilde{Y}_0 \xleftrightarrow{\epsilon} \tilde{X}_{-\mu} \xleftrightarrow{\epsilon} \tilde{X}_{-\mu-\nu}$ is an ϵ -Markov chain, we can write

$$I_L(\tilde{Y}_0; \tilde{X}_{-k-1} | \tilde{X}_{-k}) = O(\epsilon). \tag{129}$$

This implies

$$g_2(\delta) = \sum_{k=0}^{\delta-1} O(\epsilon) = O(\epsilon). \tag{130}$$

The last equality follows from the summation property of big- O -notation. This completes the proof.

APPENDIX J PROOF OF THEOREM 2

Using (12) and Theorem 1, we obtain

$$\begin{aligned}
& H_L(\tilde{Y}_0 | \tilde{X}_{-\Theta}, \Theta) \\
&= \sum_{\delta \in \mathbb{Z}^+} P_{\Theta}(\delta) (H_L(\tilde{Y}_0 | \tilde{X}_0) + \hat{g}_1(\delta) - g_2(\delta)) \\
&= H_L(\tilde{Y}_0 | \tilde{X}_0) + \mathbb{E}_{\Theta \sim P_{\Theta}}[\hat{g}_1(\Theta)] - \mathbb{E}_{\Theta \sim P_{\Theta}}[g_2(\Theta)], \tag{131}
\end{aligned}$$

where

$$\begin{aligned}
\hat{g}_1(\delta) &= g_1(\delta) - H_L(\tilde{Y}_0 | \tilde{X}_0) \\
&= \sum_{k=0}^{\delta-1} I_L(\tilde{Y}_0; \tilde{X}_{-k} | \tilde{X}_{-k-1}). \tag{132}
\end{aligned}$$

Because mutual information $I_L(\tilde{Y}_0; \tilde{X}_{-k} | \tilde{X}_{-k-1})$ is non-negative, we have

$$\hat{g}_1(\delta) = \sum_{k=0}^{\delta-1} I_L(\tilde{Y}_0; \tilde{X}_{-k} | \tilde{X}_{-k-1}) \geq 0. \tag{133}$$

Because $\hat{g}_1(\delta)$ is non-negative for all δ , the function $\hat{g}_1(\cdot)$ is Lebesgue integrable with respect to all probability measure P_{Θ} [61]. Hence, the expectation $\mathbb{E}_{\Theta \sim P_{\Theta}}[\hat{g}_1(\Theta)]$ exists. Note that $E_{\Theta \sim P_{\Theta}}[\hat{g}_1(\Theta)]$ can be infinite ($+\infty$). By using the same argument, we obtain that $E_{\Theta \sim P_{\Theta}}[g_2(\Theta)]$ exists but can also be infinite. Moreover, the functions $\hat{g}_1(\delta)$ and $g_2(\delta)$ are non-decreasing in δ .

Because (i) the function $\hat{g}_1(\delta)$ is non-decreasing in δ , (ii) the expectation $\mathbb{E}_{\Theta \sim P_{\Theta}}[\hat{g}_1(\Theta)]$ exists, and (iii) $\Theta_1 \leq_{st} \Theta_2$, we have [44]

$$\mathbb{E}_{\Theta \sim P_{\Theta_1}}[\hat{g}_1(\Theta)] \leq \mathbb{E}_{\Theta \sim P_{\Theta_2}}[\hat{g}_1(\Theta)]. \tag{134}$$

Next, we obtain:

$$\begin{aligned}
& H_L(\tilde{Y}_0 | \tilde{X}_{-\Theta_1}, \Theta_1) \\
&\stackrel{(a)}{=} H_L(\tilde{Y}_0 | \tilde{X}_0) + \mathbb{E}_{\Theta \sim P_{\Theta_1}}[\hat{g}_1(\Theta)] - \mathbb{E}_{\Theta \sim P_{\Theta_1}}[g_2(\Theta)] \\
&\stackrel{(b)}{\leq} H_L(\tilde{Y}_0 | \tilde{X}_0) + \mathbb{E}_{\Theta \sim P_{\Theta_2}}[\hat{g}_1(\Theta)] - \mathbb{E}_{\Theta \sim P_{\Theta_1}}[g_2(\Theta)] \\
&\stackrel{(c)}{=} H_L(\tilde{Y}_0 | \tilde{X}_{-\Theta_2}, \Theta_2) \\
&\quad + \mathbb{E}_{\Theta \sim P_{\Theta_2}}[g_2(\Theta)] - \mathbb{E}_{\Theta \sim P_{\Theta_1}}[g_2(\Theta)] \\
&\stackrel{(d)}{=} H_L(\tilde{Y}_0 | \tilde{X}_{-\Theta_2}, \Theta_2) + O(\epsilon), \tag{135}
\end{aligned}$$

where (a) and (c) hold due to (131), (b) is obtained using (134), and (d) follows from the fact that $\tilde{Y}_0 \xleftrightarrow{\epsilon} \tilde{X}_{-\mu} \xleftrightarrow{\epsilon} \tilde{X}_{-\mu-\nu}$ is an ϵ -Markov chain for all $\mu, \nu \geq 0$ (see Theorem 1(b)). This completes the proof.

APPENDIX K PROOF OF LEMMA 3

By using condition (26) and Lemma 7(a), we obtain for all $x \in \mathcal{X}$:

$$D_L(P_{Y_t | X_{t-\delta}=x} \| P_{\tilde{Y}_0 | \tilde{X}_{-\delta}=x}) = O(\beta). \tag{136}$$

Next, by using (13) and (136), we have

$$\begin{aligned}
& H_L(P_{Y_t|X_{t-\delta}}; P_{\tilde{Y}_0|X_{-\delta}}|P_{X_{t-\delta}}) \\
&= H_L(Y_t|X_{t-\delta}) \\
&+ \sum_{x \in \mathcal{X}} P_{X_{t-\delta}}(x) D_L \left(P_{Y_t|X_{t-\delta}=x} || P_{\tilde{Y}_0|\tilde{X}_{-\delta}=x} \right) \\
&= H_L(Y_t|X_{t-\delta}) + O(\beta). \tag{137}
\end{aligned}$$

This completes the proof.

APPENDIX L PROOF OF THEOREM 3

Part (a): By the definition of L -conditional cross entropy (13), we get

$$\begin{aligned}
& H_L(P_{Y_t|X_{t-\delta}}; P_{\tilde{Y}_0|X_{-\delta}}|P_{X_{t-\delta}}) \\
&= \sum_{x \in \mathcal{X}} P_{X_{t-\delta}}(x) \mathbb{E}_{Y \sim P_{Y_t|X_{t-\delta}=x}} \left[L \left(Y, a_{\tilde{Y}_0|\tilde{X}_{-\delta}=x} \right) \right], \tag{138}
\end{aligned}$$

where the Bayes predictor $a_{\tilde{Y}_0|\tilde{X}_{-\delta}=x}$ is fixed in the inference phase for every time slot t . Because $\{(Y_t, X_t), t = 0, 1, 2, \dots\}$ is a stationary process, (138) is a function of the AoI δ .

Part (b): We can apply Lemma 3 since (26) holds for all $x \in \mathcal{X}$ and $\delta \in \mathcal{Z}^+$. This gives us:

$$\begin{aligned}
& H_L(P_{Y_t|X_{t-\delta_1}}; P_{\tilde{Y}_0|X_{-\delta_1}}|P_{X_{t-\delta_1}}) \\
&= H_L(Y_t|X_{t-\delta_1}) + O(\beta) \\
&\leq H_L(Y_t|X_{t-\delta_2}) + O(\epsilon) + O(\beta) \\
&= H_L(P_{Y_t|X_{t-\delta_2}}; P_{\tilde{Y}_0|X_{-\delta_2}}|P_{X_{t-\delta_2}}) + O(\beta) + O(\epsilon) + O(\beta) \\
&= H_L(P_{Y_t|X_{t-\delta_2}}; P_{\tilde{Y}_0|X_{-\delta_2}}|P_{X_{t-\delta_2}}) + O(\max\{\epsilon, \beta\}), \tag{139}
\end{aligned}$$

where we use Lemma 3 to obtain the first and the third equality, and the second inequality holds due to the assumption that $Y_t \overset{\epsilon}{\leftrightarrow} X_{t-\mu} \overset{\epsilon}{\leftrightarrow} X_{t-\mu-\nu}$ is an ϵ -Markov chain for all $\mu, \nu \geq 0$ (see Theorem 1). This completes the proof.

APPENDIX M PROOF OF THEOREM 4, THEOREM 5, THEOREM 7, AND THEOREM 8

In this section, we prove Theorem 4, Theorem 5, Theorem 7, and Theorem 8. These theorems provide optimal solutions for the scheduling problems (33), (34), (58), and (59). We begin by deriving the optimal solution for (58). Subsequently, the optimal solutions for (33), (34), and (59) follow directly, as these problems are special cases of (58).

Since the problem (58) focuses solely on a single source, we simplify the notation by omitting the source index m and rewrite the problem (58) as follows:

$$\bar{p}_{opt}(\lambda) = \inf_{\pi \in \Pi} \limsup_{T \rightarrow \infty} \mathbb{E} \left[\frac{1}{T} \sum_{t=0}^{T-1} w p(\Delta(t)) + \lambda c(t) \right], \tag{140}$$

where $p(\Delta(t))$ is the penalty at time t , $\Delta(t) \in \mathbb{Z}^+$ is the AoI, $c(t) \in \{0, 1\}$ is the channel occupation status at time t , $\pi = ((S_1, b_1), (S_2, b_2), \dots)$ is a scheduling policy, Π is the set of all causal and signal-agnostic scheduling policies, $w > 0$ is a weight, and $\bar{p}_{opt}(\lambda)$ is the optimal objective value to (140).

The scheduling problem (140) is an infinite-horizon average-cost semi-Markov decision process (SMDP) [48, Chapter 5.6]. We provide a detailed description of the components of this problem:

- **Decision Time:** Each i -th feature delivery time $D_i = S_i + T_i$ is a decision time of the problem (140), where S_i is the scheduling time of the i -th feature and the i -th feature takes $T_i \geq 1$ time slots to be delivered.
 - **State:** At time slot D_i , the state of the system is represented by AoI $\Delta(D_i)$.
 - **Action:** Let $\tau_{i+1} = S_{i+1} - D_i$ represent the waiting time for sending the $(i+1)$ -th feature after the i -th feature is delivered. As we consider $S_0 = 0$ and $S_i = \sum_{j=1}^i (T_{j-1} + \tau_j)$ for each $i = 1, 2, \dots$. Given (T_0, T_1, \dots) , the sequence (S_1, S_2, \dots) is uniquely determined by (τ_1, τ_2, \dots) . Hence, one can also use (τ_1, τ_2, \dots) to represent a sequence of actions instead of (S_1, S_2, \dots) .
- At time D_i , the scheduler decides the waiting time τ_{i+1} and the buffer position b_{i+1} .
- **State Transitions:** The AoI process $\Delta(t)$ evolves as

$$\Delta(t) = \begin{cases} T_i + b_i, & \text{if } t = D_i, i = 0, 1, \dots, \\ \Delta(t-1) + 1, & \text{otherwise.} \end{cases} \tag{141}$$

- **Expected Transition Time:** The expected time difference between two decision times, D_i and D_{i+1} , is given by

$$\begin{aligned}
\mathbb{E}[D_{i+1} - D_i] &= \mathbb{E}[S_{i+1} + T_{i+1} - (S_i + T_i)] \\
&= \mathbb{E}[S_i + T_i + \tau_{i+1} + T_{i+1} - S_i - T_i] \\
&= \mathbb{E}[\tau_{i+1} + T_{i+1}]. \tag{142}
\end{aligned}$$

- **Expected Transition Cost:** The expected cumulative cost incurred during the interval between two decision times, D_i and D_{i+1} , can be calculated as

$$\begin{aligned}
& \mathbb{E} \left[\sum_{t=D_i}^{D_{i+1}-1} \left(w p(\Delta(t)) + \lambda c(t) \right) \right] \\
&= \mathbb{E} \left[\sum_{k=0}^{\tau_{i+1} + T_{i+1} - 1} w p(\Delta(D_i + k)) \right] + \lambda \mathbb{E}[T_{i+1}]. \tag{143}
\end{aligned}$$

The infinite-horizon average-cost SMDP (140) can be solved by using dynamic programming [48], [62]. Let $h : \mathbb{Z}^+ \mapsto \mathbb{R}$ be the relative value function associated with the average-cost SMDP (140). At time $t = D_i$, the optimal action (τ_{i+1}, b_{i+1}) can be determined by solving the following Bellman optimal-

ity equation [48, P. 275]:

$$\begin{aligned}
& h(\Delta(D_i)) \\
&= \inf_{\substack{\tau_{i+1} \in \{0,1,\dots\} \\ b_{i+1} \in \{0,\dots,B-1\}}} \mathbb{E} \left[\sum_{k=0}^{\tau_{i+1}+T_{i+1}-1} wp(\Delta(D_i+k)) \right] + \lambda \mathbb{E}[T_{i+1}] \\
&\quad - \bar{p}_{opt}(\lambda) \mathbb{E}[\tau_{i+1} + T_{i+1}] + \mathbb{E}[h(\Delta(D_{i+1}))] \\
&= \inf_{\substack{\tau_{i+1} \in \{0,1,\dots\} \\ b_{i+1} \in \{0,\dots,B-1\}}} \mathbb{E} \left[\sum_{k=0}^{\tau_{i+1}+T_{i+1}-1} \left(wp(\Delta(D_i+k)) - \bar{p}_{opt}(\lambda) \right) \right] \\
&\quad + \lambda \mathbb{E}[T_{i+1}] + \mathbb{E}[h(\Delta(D_{i+1}))] \\
&= \inf_{\substack{\tau_{i+1} \in \{0,1,\dots\} \\ b_{i+1} \in \{0,\dots,B-1\}}} \mathbb{E} \left[\sum_{k=0}^{\tau_{i+1}+T_{i+1}-1} \left(wp(\Delta(D_i+k)) - \bar{p}_{opt}(\lambda) \right) \right] \\
&\quad + \lambda \mathbb{E}[T_{i+1}] + \mathbb{E}[h(T_{i+1} + b_{i+1})], \quad (144)
\end{aligned}$$

where the last equality holds because $\Delta(D_{i+1}) = T_{i+1} + b_{i+1}$.

From (144), it is observed that the buffer position b_{i+1} only depends on the term $\mathbb{E}[h(T_{i+1} + b_{i+1})]$, while the waiting time τ_{i+1} has no impact on $\mathbb{E}[h(T_{i+1} + b_{i+1})]$. Hence, the optimal buffer position b_{i+1}^* is determined by

$$b_{i+1}^* = \arg \min_{b_{i+1} \in \{0,1,\dots,B-1\}} \mathbb{E}[h(T_{i+1} + b_{i+1})]. \quad (145)$$

Since T_i 's are i.i.d., $\mathbb{E}[h(T_{i+1} + b)] = \mathbb{E}[h(T_i + b)] = \dots = \mathbb{E}[h(T_1 + b)]$ for all i and b . Hence, from (145), it is evident that there exists a $b^* \in \{0, 1, \dots, B-1\}$ such that $b_1^* = b_2^* = \dots = b_{i+1}^* = b^*$ that satisfies

$$b^* = \arg \min_{b \in \{0,1,\dots,B-1\}} \mathbb{E}[h(T_1 + b)]. \quad (146)$$

Because the optimal buffer position is time-invariant, the problem (140) can be expressed as

$$\bar{p}_{opt}(\lambda) = \min_{b \in \{0,1,\dots,B-1\}} \bar{p}_{b,opt}(\lambda), \quad (147)$$

where $\bar{p}_{b,opt}(\lambda)$ is given by

$$\bar{p}_{b,opt}(\lambda) = \inf_{\pi_b \in \Pi_b} \limsup_{T \rightarrow \infty} \frac{1}{T} \mathbb{E}_{\pi_b} \left[\sum_{t=0}^{T-1} w p(\Delta(t)) + \lambda c(t) \right], \quad (148)$$

$\pi_b = ((S_1, b), (S_2, b), \dots)$, Π_b is the set of all causal and signal-agnostic scheduling policies π_b with fixed buffer position b , and $\bar{p}_{b,opt}(\lambda)$ is the optimal objective value to (148).

At every i -th decision time D_i of the average-cost SMDP (148), the scheduler decides the waiting time τ_{i+1} . The average-cost SMDP (148) can be solved by using dynamic programming [48], [62]. Given AoI value δ at decision time D_i , the Bellman optimality equation of (148) is obtained by

substituting $\Delta(D_i) = \delta$, $b_{i+1} = b$, and $\bar{p}_{opt}(\lambda) = \bar{p}_{b,opt}(\lambda)$ into (144), given by

$$\begin{aligned}
h_b(\delta) &= \inf_{\tau \in \{0,1,2,\dots\}} \mathbb{E} \left[\sum_{k=0}^{\tau+T_{i+1}-1} (w p(\delta+k) - \bar{p}_{b,opt}(\lambda)) \right] \\
&\quad + \lambda \mathbb{E}[T_{i+1}] + \mathbb{E}[h_b(T_{i+1} + b)], \quad \delta = 1, 2, \dots \\
&= \inf_{\tau \in \{0,1,2,\dots\}} \mathbb{E} \left[\sum_{k=0}^{\tau+T_1-1} (w p(\delta+k) - \bar{p}_{b,opt}(\lambda)) \right] \\
&\quad + \lambda \mathbb{E}[T_1] + \mathbb{E}[h_b(T_1 + b)], \quad \delta = 1, 2, \dots, \quad (149)
\end{aligned}$$

where the last equality holds because T_i 's are identically distributed. Let $\tau(\delta, \bar{p}_{b,opt}(\lambda))$ be an optimal solution to (149). If $\Delta(D_i) = \delta$, then an optimal waiting time τ_{i+1} of (148) for sending the $(i+1)$ -th feature is $\tau(\delta, \bar{p}_{b,opt}(\lambda))$.

From (149), we can show that $\tau(\delta, \bar{p}_{b,opt}(\lambda)) = 0$ if

$$\begin{aligned}
& \inf_{\tau \in \{1,2,\dots\}} \mathbb{E} \left[\sum_{k=0}^{\tau+T_1-1} (w p(\delta+k) - \bar{p}_{b,opt}(\lambda)) \right] \\
& \geq \mathbb{E} \left[\sum_{k=0}^{T_1-1} (w p(\delta+k) - \bar{p}_{b,opt}(\lambda)) \right]. \quad (150)
\end{aligned}$$

After some rearrangement, the inequality (150) can also be expressed as

$$\inf_{\tau \in \{1,2,\dots\}} \mathbb{E} \left[\sum_{k=0}^{\tau-1} (w p(\delta+k+T_1) - \bar{p}_{b,opt}(\lambda)) \right] \geq 0. \quad (151)$$

Next, similar to [9, Lemma 7], the following lemma holds.

Lemma 8. *The inequality (151) holds if and only if*

$$\inf_{\tau \in \{1,2,\dots\}} \frac{1}{\tau} \mathbb{E} \left[\sum_{k=0}^{\tau-1} w p(\delta+k+T_1) \right] \geq \bar{p}_{b,opt}(\lambda). \quad (152)$$

According to (36), the left-hand side of (152) is equal to $\gamma(\delta)$. Similarly, $\tau(\delta, \bar{p}_{b,opt}(\lambda)) = 1$, if $\tau(\delta, \bar{p}_{b,opt}(\lambda)) \neq 0$ and

$$\inf_{\tau \in \{2,3,\dots\}} \mathbb{E} \left[\sum_{k=0}^{\tau-1} (w p(\delta+k+T_1) - \bar{p}_{b,opt}(\lambda)) \right] \geq 0 \quad (153)$$

By using Lemma 8 and (36), we can show that the inequality (153) can be rewritten as

$$\gamma(\delta+1) \geq \bar{p}_{b,opt}(\lambda). \quad (154)$$

By repeating this process, we get $\tau(\delta, \bar{p}_{b,opt}(\lambda)) = k$ is optimal, if $\tau(\delta, \bar{p}_{b,opt}(\lambda)) \neq 0, 1, \dots, k-1$ and

$$\gamma(\delta+k) \geq \bar{p}_{b,opt}(\lambda). \quad (155)$$

Hence, the optimal waiting time $\tau_{i+1} = \tau(\delta, \bar{p}_b(\lambda))$ is determined by

$$\tau(\delta, \bar{p}_b(\lambda)) = \min_{k \in \mathbb{Z}} \{k \geq 0 : \gamma(\delta+k) \geq \bar{p}_{b,opt}(\lambda)\}. \quad (156)$$

Now, we are ready to compute the optimal objective value $\bar{p}_{b,opt}(\lambda)$. Using (149), we can determine the value of $\mathbb{E}[h_b(T_1 + b)]$, which is given by

$$\begin{aligned} & \mathbb{E}[h_b(T_1 + b)] \\ &= \mathbb{E} \left[\sum_{k=0}^{\tau(T_1+b, \bar{p}_{b,opt}(\lambda))+T_1-1} (wp(T_1 + b + k) - \bar{p}_{b,opt}(\lambda)) \right] \\ &+ \lambda \mathbb{E}[T_1] + \mathbb{E}[h_b(T_1 + b)], \end{aligned} \quad (157)$$

which yields

$$\begin{aligned} & \mathbb{E} \left[\sum_{k=0}^{\tau(T_1+b, \bar{p}_{b,opt}(\lambda))+T_1-1} (wp(T_1 + b + k) - \bar{p}_{b,opt}(\lambda)) \right] \\ &+ \lambda \mathbb{E}[T_1] = 0. \end{aligned} \quad (158)$$

Rearranging (158), we get

$$\begin{aligned} & \bar{p}_{b,opt}(\lambda) \\ &= \frac{\mathbb{E} \left[\sum_{k=0}^{\tau(T_1+b, \bar{p}_{b,opt}(\lambda))+T_1-1} wp(T_1 + b + k) \right] + \lambda \mathbb{E}[T_1]}{\mathbb{E}[\tau(T_1 + b, \bar{p}_{b,opt}(\lambda)) + T_1]} \\ &= \frac{\mathbb{E} \left[\sum_{t=D_i(\bar{p}_{b,opt}(\lambda))}^{D_{i+1}(\bar{p}_{b,opt}(\lambda))-1} wp(\Delta(t)) \right] + \lambda \mathbb{E}[T_1]}{\mathbb{E}[D_{i+1}(\bar{p}_{b,opt}(\lambda)) - D_i(\bar{p}_{b,opt}(\lambda))]}, \end{aligned} \quad (159)$$

where $D_{i+1}(\bar{p}_{b,opt}(\lambda)) = S_{i+1}(\bar{p}_{b,opt}(\lambda)) + T_{i+1}$ and

$$\begin{aligned} & S_{i+1}(\bar{p}_{b,opt}(\lambda)) \\ &= \min_{t \geq 0} \{t \geq D_i(\bar{p}_{b,opt}(\lambda)) : \gamma(\Delta(t)) \geq \bar{p}_{b,opt}(\lambda)\}, \end{aligned} \quad (160)$$

and the last equality holds due to (142) and (143).

Now, by combining (147), (156), and (159) and by substituting appropriate values of λ and w , we obtain optimal solution to (34), (33), (58), and (59).

Finally, we need to prove that

$$\begin{aligned} & \mathbb{E} \left[\sum_{t=D_i(\beta)}^{D_{i+1}(\beta)-1} wp(\Delta(t)) \right] \\ &- \beta \mathbb{E}[D_{i+1}(\beta) - D_i(\beta)] + \lambda \mathbb{E}[T_1] = 0. \end{aligned} \quad (161)$$

has a unique root. We define

$$\begin{aligned} J(\beta) &= \mathbb{E} \left[\sum_{t=D_i(\beta)}^{D_{i+1}(\beta)-1} wp(\Delta(t)) \right] \\ &- \beta \mathbb{E}[D_{i+1}(\beta) - D_i(\beta)] + \lambda \mathbb{E}[T_1]. \end{aligned} \quad (162)$$

Lemma 9. *The function $J(\beta)$ has the following properties:*

- (i) *The function $J(\beta)$ is concave, continuous, and strictly decreasing in β .*
- (ii) *$\lim_{\beta \rightarrow \infty} j(\beta) = -\infty$ and $\lim_{\beta \rightarrow -\infty} j(\beta) = \infty$.*

Proof. See Appendix S □

Lemma 9 proves the uniqueness of (196). Also, the uniqueness of the root of (37) and (62) follows immediately from Lemma 9.

APPENDIX N PROOF OF THEOREM 9

According to (64) and the definition of set $\Omega_m(\lambda)$, a point $(\Delta_m(t), d_m(t)) \in \Omega_m(\lambda)$ if either (i) $d_m(t) > 0$ such that a feature from source m is currently in service at time t , or (ii) $\gamma_m(\Delta_m(t)) < \bar{p}_{m,opt}(\lambda)$ such that the threshold condition in (64) for sending a new feature is not satisfied. By this, an analytical expression of set $\Omega_m(\lambda)$ is derived as

$$\Omega_m(\lambda) = \{(\delta, d) : d > 0 \text{ or } \gamma_m(\delta) < \bar{p}_{m,opt}(\lambda)\}, \quad (163)$$

where according to Theorem 7 and Theorem 8, $\beta = \bar{p}_{m,opt}(\lambda)$ is the unique root of

$$J_{m,1}(\beta) + \lambda \mathbb{E}[T_{m,1}] = 0, \quad (164)$$

and

$$\begin{aligned} J_{m,1}(\beta) &= \mathbb{E} \left[\sum_{t=D_{m,i}(\beta)}^{D_{m,i+1}(\beta)-1} w_m p_m(\Delta_m(t)) \right] \\ &- \beta \mathbb{E}[D_{m,i+1}(\beta) - D_{m,i}(\beta)]. \end{aligned} \quad (165)$$

Because $\lambda \mathbb{E}[T_{m,1}]$ does not change with β , from Lemma 9, we can show that $J_{m,1}(\beta)$ is a strictly decreasing function of β with $\lim_{\beta \rightarrow \infty} j_{m,1}(\beta) = -\infty$ and $\lim_{\beta \rightarrow -\infty} j_{m,1}(\beta) = \infty$. Hence, the inverse function $J_{m,1}^{-1}(\cdot)$ exists and from (164), we get $J_{m,1}^{-1}(\lambda \mathbb{E}[T_{m,1}]) = \bar{p}_{m,opt}(\lambda)$. Because the inverse function of a strictly decreasing function is strictly increasing, $\bar{p}_{m,opt}(\lambda)$ is strictly increasing function of λ . Substituting this into (163), we get that if $\lambda_1 \leq \lambda_2$, then $\Omega_m(\lambda_1) \subseteq \Omega_m(\lambda_2)$.

For dummy bandits, it is optimal in (57) to activate a dummy bandit when $\lambda \leq 0$. Hence, dummy bandits are always indexable.

APPENDIX O PROOF OF THEOREM 10

By substituting (163) into (67), we obtain, if $d > 0$, then $W_m(\delta, d) = -\infty$, and if $d = 0$, then

$$W_m(\delta, 0) = \inf\{\lambda : \gamma_m(\delta) < \bar{p}_{m,opt}(\lambda)\}. \quad (166)$$

Using (65) and (166), we get

$$W_m(\delta, 0) = \max_{0 \leq b \leq B_m - 1} W_{m,b}(\delta, 0), \quad (167)$$

where

$$W_{m,b}(\delta, 0) = \inf\{\lambda : \gamma_m(\delta) < \bar{p}_{m,b,opt}(\lambda)\}. \quad (168)$$

Because $\bar{p}_{m,b,opt}(\lambda)$ is strictly increasing function of λ , (168) implies that $W_{m,b}(\delta, 0)$ is unique and satisfies

$$\bar{p}_{m,b,opt}(W_{m,b}(\delta, 0)) = \gamma_m(\delta). \quad (169)$$

By including source index m into (159), we get

$$\begin{aligned} & \bar{p}_{m,b,opt}(\lambda) \\ &= \frac{\mathbb{E} \left[\sum_{t=D_{m,i}(\bar{p}_{m,b,opt}(\lambda))}^{D_{m,i+1}(\bar{p}_{m,b,opt}(\lambda))-1} p_m(\Delta_m(t)) \right] + \lambda \mathbb{E}[T_{m,1}]}{\mathbb{E}[D_{m,i+1}(\bar{p}_{m,b,opt}(\lambda)) - D_{m,i}(\bar{p}_{m,b,opt}(\lambda))]} \end{aligned} \quad (170)$$

By substituting $\lambda = W_{m,b}(\delta, 0)$ and (169) into (170), and then, re-arranging, we get (69). This concludes the proof.

APPENDIX P
PROOF OF LEMMA 7

To prove Lemma 7, we will use the sub-gradient mean value theorem [63]. When $H_L(Y)$ is twice differentiable in P_Y , we can use a second order Taylor series expansion.

If (121) holds, we can obtain

$$\sum_{y \in \mathcal{Y}} (P_Y(y) - Q_Y(y))^2 \leq \beta^2, \quad (171)$$

$$\sum_{y \in \mathcal{Y}} |P_Y(y) - Q_Y(y)| \leq \beta, \quad (172)$$

and

$$\max_{y \in \mathcal{Y}} |P_Y(y) - Q_Y(y)| \leq \beta. \quad (173)$$

Let us define a convex function $g : \mathbb{R}^{|\mathcal{Y}|} \mapsto \mathbb{R}$ as

$$g(\mathbf{z}) = \sum_{i=1}^{|\mathcal{Y}|} z_i L(y_i, a_{Q_Y}) - \min_{a \in \mathcal{A}} \sum_{i=1}^{|\mathcal{Y}|} z_i L(y_i, a), \quad (174)$$

where a_{Q_Y} is a Bayes action associated with the distribution Q_Y , i.e., a_{Q_Y} is the minimizer of

$$a_{Q_Y} = \arg \min_{a \in \mathcal{A}} \mathbb{E}_{Y \sim Q_Y} [L(Y, a)]. \quad (175)$$

Because $g(\mathbf{z})$ is a convex function and the set of sub-gradients of $g(\mathbf{z})$ is bounded [63, Proposition 4.2.3], we can apply the sub-gradient mean value theorem [63] along with (85), and (172) to obtain

$$\begin{aligned} g(\mathbf{p}_Y) &= D_L(P_Y \| Q_Y) \\ &= g(\mathbf{q}_Y) + O\left(\sum_{y \in \mathcal{Y}} |P_Y(y) - Q_Y(y)|\right) \\ &= D_L(Q_Y \| Q_Y) + O\left(\sum_{y \in \mathcal{Y}} |P_Y(y) - Q_Y(y)|\right) \\ &= O(\beta). \end{aligned} \quad (176)$$

Now, let us consider the case where $H_L(Y)$ is assumed to be twice differentiable in P_Y . The function $g(\mathbf{p}_Y)$ can also be expressed in terms of $H_L(Y)$ as:

$$\begin{aligned} g(\mathbf{p}_Y) &= \sum_{i=1}^{|\mathcal{Y}|} P_Y(y_i) L(y_i, a_{Q_Y}) - \min_{a \in \mathcal{A}} \sum_{i=1}^{|\mathcal{Y}|} P_Y(y_i) L(y_i, a) \\ &= \sum_{i=1}^{|\mathcal{Y}|} P_Y(y_i) L(y_i, a_{Q_Y}) - H_L(Y). \end{aligned} \quad (177)$$

Because $H_L(Y)$ is assumed to be twice differentiable in P_Y , from (177), we can conclude that $g(\mathbf{p}_Y)$ is twice differentiable with respect to \mathbf{p}_Y . Furthermore, we have

$$g(\mathbf{p}_Y) \geq 0, \forall \mathbf{p}_Y \in \mathbb{R}^{|\mathcal{Y}|} \quad (178)$$

and

$$g(\mathbf{q}_Y) = D_L(Q_Y \| Q_Y) = 0. \quad (179)$$

Using the first-order necessary condition for optimality, we find that the gradient of $g(\mathbf{p}_Y)$ at point $\mathbf{p}_Y = \mathbf{q}_Y$ is zero, i.e.,

$$\nabla g(\mathbf{q}_Y) = 0. \quad (180)$$

Next, based on (179) and (180), we can perform a second-order Taylor series expansion of $g(\mathbf{p}_Y)$ at $\mathbf{p}_Y = \mathbf{q}_Y$:

$$\begin{aligned} g(\mathbf{p}_Y) &= g(\mathbf{q}_Y) + (\mathbf{p}_Y - \mathbf{q}_Y)^T \nabla g(\mathbf{q}_Y) \\ &\quad + \frac{1}{2} (\mathbf{p}_Y - \mathbf{q}_Y)^T \mathcal{H}(\mathbf{q}_Y) (\mathbf{p}_Y - \mathbf{q}_Y) \\ &\quad + o\left(\sum_{y \in \mathcal{Y}} (P_Y(y) - Q_Y(y))^2\right) \\ &= \frac{1}{2} (\mathbf{p}_Y - \mathbf{q}_Y)^T \mathcal{H}(\mathbf{q}_Y) (\mathbf{p}_Y - \mathbf{q}_Y) \\ &\quad + o\left(\sum_{y \in \mathcal{Y}} (P_Y(y) - Q_Y(y))^2\right), \end{aligned} \quad (181)$$

where $\mathcal{H}(\mathbf{q}_Y)$ is the Hessian matrix of $g(\mathbf{p}_Y)$ at point $\mathbf{p}_Y = \mathbf{q}_Y$.

Because $g(\mathbf{p}_Y)$ is a convex function, we have

$$(\mathbf{p}_Y - \mathbf{q}_Y)^T \mathcal{H}(\mathbf{q}_Y) (\mathbf{p}_Y - \mathbf{q}_Y) \geq 0.$$

Moreover, we can express

$$\begin{aligned} &\frac{1}{2} (\mathbf{p}_Y - \mathbf{q}_Y)^T \mathcal{H}(\mathbf{q}_Y) (\mathbf{p}_Y - \mathbf{q}_Y) \\ &= \frac{1}{2} \sum_{y, y'} (P_Y(y) - Q_Y(y)) \mathcal{H}(\mathbf{q}_Y)_{y, y'} (P_Y(y') - Q_Y(y')) \\ &= O\left(\sum_{y, y'} (P_Y(y) - Q_Y(y)) (P_Y(y') - Q_Y(y'))\right). \end{aligned} \quad (182)$$

Now, by substituting (182) into (181), we obtain

$$\begin{aligned} g(\mathbf{p}_Y) &= O\left(\sum_{y, y'} (P_Y(y) - Q_Y(y)) (P_Y(y') - Q_Y(y'))\right) \\ &\quad + o\left(\sum_{y \in \mathcal{Y}} (P_Y(y) - Q_Y(y))^2\right). \end{aligned} \quad (183)$$

Using (171) and (173), we obtain from (183) that

$$g(\mathbf{p}_Y) = D_L(P_Y \| Q_Y) = O(\beta^2) + o(\beta^2) = O(\beta^2). \quad (184)$$

This completes the proof.

APPENDIX Q
PROOF OF LEMMA 4

Because $Y_t = f(X_{t-d})$ and X_t is a Markov chain, $Y_t \leftrightarrow X_{t-d} \leftrightarrow X_{t-(d-1)}$ is a Markov chain for all $0 \leq \delta \leq d$. By the data processing inequality for L -conditional entropy [35, Lemma 12.1], one can show that for all $0 \leq \delta \leq d$,

$$H_L(Y_t | X_{t-\delta}) \leq H_L(Y_t | X_{t-(\delta-1)}). \quad (185)$$

Moreover, since $Y_t = f(X_{t-d})$ and X_t is a Markov chain, $Y_t \leftrightarrow X_{t-d} \leftrightarrow X_{t-(\delta+1)}$ is a Markov chain for all $\delta \geq d$.

By the data processing inequality [35, Lemma 12.1], one can show that for all $\delta \geq d$,

$$H_L(Y_t|X_{t-\delta}) \leq H_L(Y_t|X_{t-(\delta+1)}). \quad (186)$$

Because $Y_t = f(X_{t-d})$ and $f(\cdot)$ is a function, we have $P_{Y_t|X_{t-d}} = P_{Y_t|f(X_{t-d})} = P_{Y_t|Y_t}$. Hence,

$$H_L(Y_t|X_{t-d}) = H_L(Y_t|Y_t) \leq H_L(Y_t|Z). \quad (187)$$

APPENDIX R PROOF OF THEOREM 11

A. Notations and Definitions

In (51)-(54), we have $M+N$ bandits with M sources and N dummy bandits, and N channels. Two bandits are considered to be in the same class if they share identical penalty functions, weights, and transition probabilities. The dummy bandits belong to the same class. However, among the remaining M sources, no two sources share the same combination of penalty function, weight, and transition probabilities. Therefore, we start with $M+1$ distinct classes of bandits. Then, we increase the number of sources rM , number of dummy bandits rN , and number of channels rN with scaling factor r , while maintaining the ratio $\frac{rM}{rN}$.

The state of a class m bandit is represented by two tuple $(\Delta_m(t), d_m(t))$, where $\Delta_m(t)$ represents the AoI and $d_m(t)$ is the amount of time spent to send the current feature from a class m bandit. Let $\mu_m(t) \in \{0, 1, \dots, B_m\}$ be the action taken for a class m bandit. If $\mu_m(t) = 0$, no feature is selected for transmission; otherwise, if $\mu_m(t) = b$, a feature from buffer position $(b-1) \in \{0, 1, \dots, B_m-1\}$ is selected for transmission. Given state (δ, d) and action μ of a class m bandit, we denote by $P_{(\delta', d'), (\delta, d)}^{m, \mu}$ the transition probability to a state (δ', d') .

Because we assume that the transmission times $T_{m,i}$ are bounded for all m and i , we can find a $d_{\text{bound}} \in \mathbb{N}$ such that $0 < T_{m,i} \leq d_{\text{bound}}$ for all m and i . Then, the amount of time $d_m(t)$ that has been spent to send the current feature of source m by time slot t is also bounded and $d_m(t) \in \{0, 1, \dots, d_{\text{bound}}\}$. Also, we observe from Figs. 1-5 that the inference error function $p_m(\delta)$ converges after a large AoI value. We can find an AoI δ_{bound} such that $p_m(\delta) = p_m(\delta_{\text{bound}})$ for all $\delta \geq \delta_{\text{bound}}$ and for all m .

We denote by $V_{\delta, d}^m(t)$ the fraction of class m bandits with $\Delta_m(t) = \delta$ and $d_m(t) = d$. Let $U_{\delta, d, \mu}^m(t)$ be the fraction of class m bandits with $\Delta_m(t) = \delta$, $d_m(t) = d$, and $\mu_m(t) = \mu$. We denote by $\tilde{V}_d^m(t)$ the fraction of class m bandits with $d_m(t) = d$ and $\Delta_m(t) > \delta_{\text{bound}}$. Moreover, let $\tilde{U}_{d, \mu}^m(t)$ be the fraction of class m bandits with $d_m(t) = d$, $\Delta_m(t) > \delta_{\text{bound}}$,

and $\mu(t) = \mu$. We define variables $v_{\delta, d}^m$, $u_{\delta, d, \mu}^m$, \tilde{v}_d^m , and $\tilde{u}_{d, \mu}^m$ for all δ, d, μ , and m as follows:

$$v_{\delta, d}^m := \limsup_{T \rightarrow \infty} \sum_{t=0}^{T-1} \frac{1}{T} \mathbb{E}[V_{\delta, d}^m(t)], \quad (188)$$

$$u_{\delta, d, \mu}^m := \limsup_{T \rightarrow \infty} \sum_{t=0}^{T-1} \frac{1}{T} \mathbb{E}[U_{\delta, d, \mu}^m(t)], \quad (189)$$

$$\tilde{v}_d^m := \limsup_{T \rightarrow \infty} \sum_{t=0}^{T-1} \frac{1}{T} \mathbb{E}[\tilde{V}_d^m(t)], \quad (190)$$

$$\tilde{u}_{d, \mu}^m := \limsup_{T \rightarrow \infty} \sum_{t=0}^{T-1} \frac{1}{T} \mathbb{E}[\tilde{U}_{d, \mu}^m(t)]. \quad (191)$$

A channel is occupied by a bandit, if either $d > 0$ or $\mu > 0$. Then, the time-averaged expected fraction of class m -bandits occupied a channel is given by

$$c_m = \sum_{\substack{\delta < \delta_{\text{bound}}, d > 0 \\ \mu = 0}} u_{\delta, d, \mu}^m + \sum_{\substack{\delta < \delta_{\text{bound}}, d = 0 \\ \mu > 0}} u_{\delta, d, \mu}^m \\ + \sum_{d > 0, \mu = 0} \tilde{u}_{d, \mu}^m + \sum_{d = 0, \mu > 0} \tilde{u}_{d, \mu}^m. \quad (192)$$

By using c_m , the time-average channel constraint (54) can be expressed as

$$\sum_{m=0}^M c_m = N. \quad (193)$$

We define the vectors $\mathbf{V}^m(t)$, $\mathbf{U}^m(t)$, \mathbf{v}^m , and \mathbf{u}^m to contain $(V_{\delta, d}^m(t), \tilde{V}_d^m(t))$, $(U_{\delta, d, \mu}^m(t), \tilde{U}_{d, \mu}^m(t))$, $(v_{\delta, d}^m, \tilde{v}_d^m)$, and $(u_{\delta, d, \mu}^m, \tilde{u}_{d, \mu}^m)$, respectively, for all $\delta = 1, 2, \dots, \delta_{\text{bound}}$, $d = 0, 1, \dots, d_{\text{bound}}$, and $\mu = 0, 1, \dots, B_m$.

Now, we provide a uniform global attractor condition. For a policy π , we can have a mapping Ψ_π of the state transitions, given by

$$\Psi_\pi((\mathbf{v}^m)_{m=1}^M) := \mathbb{E}_\pi[(\mathbf{V}^m(t))_{m=1}^M(t+1) | (\mathbf{V}^m(t))_{m=1}^M(t) = (\mathbf{v}^m)_{m=1}^M]. \quad (194)$$

We define the t -th iteration of the maps $\Psi_{\pi, t \geq 0}(\cdot)$ as $\Psi_{\pi, 0}((\mathbf{v}^m)_{m=1}^M) = (\mathbf{v}^m)_{m=1}^M$ and $\Psi_{\pi, t+1}((\mathbf{v}^m)_{m=1}^M) = \Psi_\pi(\Psi_{\pi, t}((\mathbf{v}^m)_{m=1}^M))$.

Definition 8. [18] *Uniform Global attractor.* An equilibrium point $(\mathbf{v}^{m*})_{m=1}^M$ associated with the optimal solution of (51)-(54) is a uniform global attractor of $\Psi_{\pi, t \geq 0}(\cdot)$, i.e., for all $\epsilon > 0$, there exists $T(\epsilon) > 0$ such that for all $t \geq T(\epsilon)$ and for all $(\mathbf{v}^m)_{m=1}^M$, one has $\|\Psi_{\pi, t}((\mathbf{v}^m)_{m=1}^M) - (\mathbf{v}^{m*})_{m=1}^M\|_1 \leq \epsilon$.

B. Asymptotic Optimality

Policy π in (51)-(54) can be expressed as a sequence of actions $\pi = (\mu(t))_{t=0,1,\dots}$, with $\mu(t) = \mu_m(t)_{m=0}^M$ representing actions taken at successive time slots. Let $(\mu^*(t))_{t=0,1,\dots}$ denote the optimal policy for solving (51)-(54). Given the optimal dual variable $\lambda = \lambda^*$, Theorems 7-8 imply that in the optimal policy for (51)-(54), class m bandits choose either action $\mu_m(t) = 0$ or $\mu_m(t) = b_m^*(\lambda^*) + 1$ at every time slot t . Therefore, the optimal state-action frequency satisfies:

$u_{\delta,d,\mu}^{m*} = 0$ for all $\mu \neq 0, b_m^*(\lambda^*) + 1$. Hence, for all class m , only two actions can occur for every bandit in class m . Thus, our multiple-action RMAB problem can be reduced to a binary action RMAB problem. After that, for the truncated state space $(\delta, d) \in \{1, 2, \dots, \delta_{\text{bound}}\} \times \{0, 1, \dots, d_{\text{bound}}\}$, we directly use [18, Theorem 13 and Proposition 14] to prove the asymptotic optimality of our policy. Though [18, Theorem 13 and Proposition 14] is proved for a single class of bandits, we can use the results for multiple classes of bandits because of a similar argument provided in [64, Section 5]: we argue that having multiple classes of bandits can be represented by a single class of bandits by considering a larger state space: the state of a bandit would be (m, δ, d) , where m is its class.

APPENDIX S
PROOF OF LEMMA 9

We denote $D_{i+1}(\beta) = S_{i+1}(\beta) + T_{i+1}$, $S_{i+1}(\beta) = \tau(\Delta(D_i), \beta) + D_i(\beta)$, where $\tau(\delta, \beta)$ is defined as the optimal solution of

$$\inf_{\tau \in \{0, 1, 2, \dots\}} \mathbb{E} \left[\sum_{k=0}^{\tau+T_1-1} (wp(\delta+k) - \beta) \right]. \quad (195)$$

Because T_i 's are i.i.d., and $\Delta(D_i) = T_i + b$, we can express (162) as

$$\begin{aligned} J(\beta) &= \mathbb{E} \left[\sum_{t=D_i(\beta)}^{D_{i+1}(\beta)-1} wp(\Delta(t)) \right] \\ &\quad - \beta \mathbb{E} [D_{i+1}(\beta) - D_i(\beta)] + \lambda \mathbb{E}[T_1] \\ &= \mathbb{E} \left[\sum_{k=0}^{\tau(T_1+b, \beta)+T_1-1} (wp(T_1 + b + k) - \beta) \right] \\ &\quad + \lambda \mathbb{E}[T_1] \\ &= \inf_{\tau \in \{0, 1, \dots\}} \mathbb{E} \left[\sum_{k=0}^{\tau+T_1-1} (wp(T_1 + b + k) - \beta) \right] \\ &\quad + \lambda \mathbb{E}[T_1]. \end{aligned} \quad (196)$$

Since the right-hand side of (196) is the pointwise infimum of the linear decreasing functions of β , $J(\beta)$ is concave, continuous, and strictly decreasing in β . This completes the proof of part (i) of Lemma 9.

Part (ii) of Lemma 9 holds because for any $\tau \geq 0$

$$\lim_{\beta \rightarrow \infty} \mathbb{E} \left[\sum_{k=0}^{\tau+T_1-1} (wp(T_1 + b + k) - \beta) \right] = -\infty \quad (197)$$

and

$$\lim_{\beta \rightarrow -\infty} \mathbb{E} \left[\sum_{k=0}^{\tau+T_1-1} (wp(T_1 + b + k) - \beta) \right] = \infty. \quad (198)$$

This completes the proof.
