ABSTRACT

Approximate K -Nearest Neighbor (AKNN) search in high-dimensional spaces is a critical yet challenging problem. The efficiency of AKNN search largely depends on the computation of distances, a process that significantly affects the runtime. To improve computational efficiency, existing work often opts for estimating *approximate distances* rather than computing exact distances, at the cost of reduced AKNN search accuracy. The recent method of ADSampling has attempted to mitigate this problem by using random projection for distance approximations and *adjusting* these approximations based on error bounds to improve accuracy. However, ADSampling faces limitations in **effectiveness** and **generality**, mainly due to the *suboptimality of its distance approximations* and its *heavy reliance on random projection matrices to obtain error bounds*. In this study, we propose a new method that uses an optimal orthogonal projection instead of random projection, thereby providing **improved distance approximations**. Moreover, our method uses error quantiles instead of error bounds for approximation adjustment, and the derivation of error quantiles can be made **independent of the projection matrix**, thus extending the generality of our approach. Extensive experiments confirm the superior efficiency and effectiveness of the proposed method. In particular, compared to the state-of-the-art method of ADSampling, our method achieves a speedup of 1.6 to 2.1 times on real datasets with almost no loss of accuracy.

1 INTRODUCTION

The problem of K -Nearest Neighbor (KNN) search in high-dimensional spaces aims to identify the top- K data points in a database S that are closest to a query point q . KNN search is of

great importance in information retrieval [26], data mining [7], recommendation systems [33], and large language models [24]. While effective solutions (such as R-trees) for KNN search exist in low-dimensional spaces, the curse of dimensionality [21] makes exact KNN search prohibitively time-consuming in high-dimensional spaces. As a result, researchers have resorted to a relaxed version of the problem, called Approximate K -Nearest Neighbor (AKNN) search, which trades accuracy for efficiency.

Given the importance of AKNN, a variety of AKNN algorithms have been proposed. These algorithms mainly include inverted file-based [3, 22], graph-based [10, 11, 25, 28, 29, 31], tree-based [5, 8, 32], and hash-based [12, 15, 19, 20, 34, 37] methods. Conceptually, to search for the AKNN of a query point q in a database S , AKNN algorithms can be abstracted into a **candidate generation-verification framework**: (1) Candidate generation: This involves selecting a subset of points from S as a superset of the returned AKNN. (2) Verification: This involves identifying the top- K points closest to q among the candidates to be returned as the AKNN.

Interestingly, the distinction between different AKNN algorithms lies mostly in the candidate generation phase. For example, inverted file-based methods (such as IVF) use clustering, while graph-based methods (such as HNSW [29]) use greedy traversal to obtain candidates. Yet, the verification phase of the AKNN algorithms is largely similar across the board. This phase maintains a result queue Q (which can be implemented as a max-heap) to preserve the data points closest to the query point q , thereby yielding the final result. Specifically, for a given candidate point p , if the distance from this point to the query point q is less than the maximum distance τ recorded in Q , the result queue is updated; otherwise, the vertex is ignored. Thus, distance computation is critical and demanding during the verification phase. In fact, **distance computation is the most time-consuming part of AKNN algorithms**. For example, for graph-based methods such as HNSW [29], distance computation accounts for 80% of the total time of AKNN search; for inverted file-based methods such as IVF, distance computation accounts for 90% of the total time cost [13]. Thus, speeding up the distance computation becomes the key to speeding up the AKNN search.

Approximate Distance Computation. To compute the (exact) distance between two points in a D -dimensional space, one could scan each dimension sequentially, resulting in a time complexity of $O(D)$. To speed up the distance computation and thus increase the efficiency of the AKNN search, an intuitive idea is to compute **approximate distances** instead of exact distances. Among these, projection and product quantization [22] are two typical approaches to computing approximate distances, each with its own suitable application scenarios. Specifically, projection methods (e.g.,

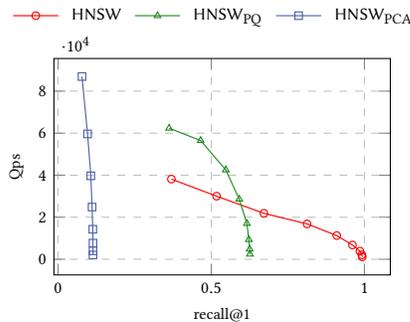

Figure 1: A comparison of search efficiency (Qps) and accuracy (Top 1-Recall) on the SIFT1M dataset. HNSW uses exact distance calculation, while HNSW_{PQ} uses Product Quantization (PQ) and HNSW_{PCA} uses PCA (with $d = 32$) for approximate distance calculation.

PCA) transform the original D -dimensional space into a new d -dimensional space (where $d < D$), thus reducing the time complexity of distance computation to $O(d)$; Product quantization methods, on the other hand, divide the original space into M subspaces, each of which has a dimension d smaller than the original dimension D . By merging the results of the subspaces via a distance look-up table, the time cost of $O(M)$ is achieved.

These two approximate distance computation methods can be combined with any AKNN algorithm. However, using approximate distances instead of exact distances greatly reduces the accuracy of the search result. The reason is that during the verification phase, incorrect approximate distances are likely to eject the true KNN points out of the result queue Q , causing the final returned data points (i.e., AKNN) to differ significantly from the actual results (i.e., KNN). For example, on the SIFT¹ dataset with one million data points, using projection methods (e.g., PCA) and product quantization methods to compute approximate distances results in a huge decrease in the recall of the top-1 result, as shown in Fig. 1.

Existing Solution. To address the shortcomings of existing distance computation methods in AKNN search, ADSampling [13] was introduced. ADSampling first computes an **approximation distance** between two points by random projection and obtains an **error bound** from the projection matrix. The advantage of ADSampling lies in its ability to use error bounds to analyze whether the use of current approximate distances in the verification phase of the AKNN search is sufficient. If not, more accurate distances are computed incrementally until finally an exact distance is calculated. ADSampling has achieved a good balance between speed and accuracy in AKNN search through adjustment by error bounds, and experimental results have confirmed its effectiveness. However, there is still significant room for improvement in its effectiveness and generality.

Effectiveness. ADSampling uses a projection method to obtain approximate distances. Specifically, ADSampling uses a *random* projection matrix to compute these approximate distances. Yet, within projection methods, a random projection matrix **cannot guarantee the minimization of the error** between approximate and exact distances. Note that if the approximate distance is sufficiently accurate, then ADSampling does not need to incrementally perform

the more time-consuming precise distance calculations. Thus, it is necessary to compute a more accurate approximate distance.

Generality. The error bound plays a critical role in ADSampling because it can determine when the calculation of approximate distances needs to be replaced by exact distance calculations to ensure accuracy. Unfortunately, obtaining the error bound for ADSampling is highly dependent on the random process of generating the projection matrix. **This makes ADSampling highly dependent on the random projection matrix**, which makes it inapplicable to approximate distances obtained by methods other than random projection.

Our Idea. To address the shortcomings in the effectiveness of ADSampling, we propose new distance computation methods in this paper. Specifically, we decompose the approximate (projected) distance to elucidate the relationship between the projection matrix and the error term (i.e., the gap between the exact distance and the approximate distance). By minimizing the error term, we find that using the optimal orthogonal projection rather than the **random** projection (as used by ADSampling) results in a theoretically optimal approximate distance. Therefore, we choose to use the orthogonal projection to obtain approximate distances to improve effectiveness.

Furthermore, inspired by the error bounds of ADSampling, we use error quantiles to adjust the approximate distance during the AKNN search. Compared to error bounds, error quantiles contain more information and thus achieve a better balance between speed and efficiency. Also, we decouple the acquisition of error quantiles from the projection matrix and propose a numerical method to **compute error quantiles directly**. Thanks to the decoupling, our method can now be adapted to arbitrary approximated distances (such as those obtained from product quantization), thereby endowing our proposed approach with the generality that ADSampling lacks. We also discuss how to incorporate the proposed approximate distances and error quantiles into the AKNN search’s verification phase in order to implement a specific AKNN algorithm.

Contributions. We summarize our contributions as follows:

Problem Analysis of the State-of-the-art. We investigated the limitations of the cutting-edge AKNN method, ADSampling. In particular, the use of random projection for ADSampling to compute approximate distances reduces its effectiveness. Furthermore, the error bound used in ADSampling is highly dependent on the random projection matrix used, rendering it difficult to adapt to other approximate distance computation methods and thus losing generality.

A New Projection-Based Distance Computation Method. To obtain the approximate distance, we found that using an optimal orthogonal projection rather than random projections (as in ADSampling) produces the smallest approximation error. In addition, inspired by the use of error bounds in ADSampling, we use a more informative error quantile to indicate when to compute exact distances to ensure accuracy. The adoption of a novel approach for obtaining approximate distance plus the utilization of error quantiles constitutes our new projection-based distance computation method. This method can be integrated with any AKNN algorithm.

A New General Distance Computation Method. We propose a general method for computing distances. Unlike ADSampling, which

Table 1: A Summary of Notations

Notation	Description
S	A set of points
D	The dimensionality of S
\mathbf{R}	The projection(rotate) matrix
\mathbb{R}^d	d -dimensional Euclidean space
dis, dis'	precise and approximate distance
N^{ef}	HNSW search parameter
N^{prob}	IVF search parameter
$\ u, v\ $	The Euclidean distance between u and v
τ	The distance threshold
L	The linear classifier

is only applicable to approximate distances obtained via random projection, our method does not impose any restrictions on how approximate distances are obtained to ensure generality. Specifically, we propose to derive error quantiles from data distributions and use a learning-based approach during the validation phase to decide whether it is necessary to compute precise distances to maintain accuracy in the AKNN search. In addition, we discuss how our general distance computation method can be integrated with existing AKNN algorithms to improve their efficiency.

Extensive Experimental Analysis. We have conducted extensive experiments on a large number of real datasets to validate our methods. The experimental results show that our methods can achieve an acceleration of 1.6 to 2.1 times compared to the state-of-the-art ADSampling. Moreover, our methods show stable performance under different parameter settings, which further illustrates the effectiveness of our methods.

Due to space limitations, some proofs have been omitted and can be found in the technical report [35].

2 PRELIMINARIES

Section 2.1 introduces AKNN search problem and algorithms. Then, Section 2.2 discusses the issue of distance computation, an essential component of AKNN search.

2.1 The AKNN Search

Given a dataset S containing n points/vectors in D -dimensional space, that is, $S = \{p_1, p_2, \dots, p_n\}$, where $p_i \in \mathbb{R}^D$. We use the squared Euclidean distance² to compute the distance $dis(p, q)$ between two points p and q , where $dis(p, q) = \|p - q\|^2$. The time complexity of computing $dis(p, q)$ is $O(D)$ by scanning each dimension sequentially. The problem of the K -Nearest Neighbor (KNN) search is to find the data points in S that are among the top- K smallest distances to a query point $q \in \mathbb{R}^D$. Note that there are other widely adopted distance metrics, such as cosine similarity and inner product, that can be transformed into Euclidean distance through simple transformations [13]. Table 1 summarizes the commonly used notation.

AKNN Algorithms. Due to the complexity of KNN search, the problem of its relaxed version — **Approximate K -Nearest Neighbors (AKNN)** search — has been proposed. Given a query point q ,

²squaring does not affect the order of distances

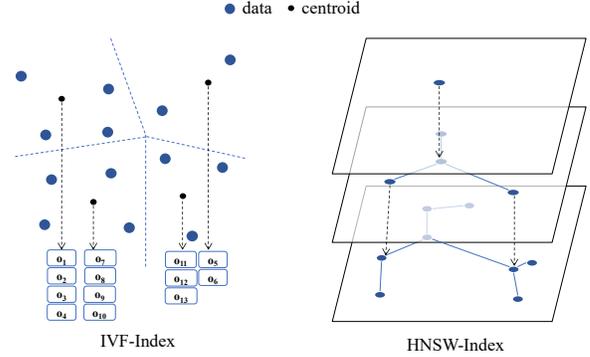

Figure 2: Example of IVF and HNSW

the AKNN search does not require the returned points to be the exact K closest points to q , thus sacrificing accuracy for computational efficiency. Currently, AKNN algorithms can be divided mainly into four categories: tree-based [8], hash-based [12, 15, 19, 20, 34, 37], Inverted File-based [3, 22], and graph-based [10, 11, 18, 25, 27, 29, 31]. *Inverted File-based Algorithms.* The basic idea behind Inverted File-based algorithms (see Fig. 2) is to use clustering to divide the points in a dataset S into multiple clusters. This is then used to speed up the AKNN search. Specifically, during the **indexing** process, IVF uses the k -means algorithm³ to cluster the data points in S , constructs a bucket for each cluster, and assigns the data points contained in that cluster to the corresponding bucket. During the **query** process, for a given query point q , IVF first selects the nearest N^{Probe} clusters based on the distance from q to the cluster centroids, retrieves all data points in the corresponding buckets of these nearest clusters as candidates, and then identifies the K nearest neighbors among these candidates. Here, N^{Probe} is a user parameter that controls the trade-off between time and accuracy: as N^{Probe} increases, more clusters are considered, thus improving accuracy at the cost of increased computation time.

Graph-based Algorithms. Graph-based algorithms for approximate nearest neighbor (ANN) search rely on the construction of a navigable graph structure where nodes represent data points and edges connect nodes that are considered nearest neighbors. Hierarchical Navigable Small World (HNSW), a state-of-the-art graph-based algorithm (see Fig. 2), has been recognized for its superior performance in terms of search speed and accuracy. To **index** HNSW, data points are inserted into a multi-layered graph structure with each layer representing the data in increasingly fine-grained detail. During insertion, each point is connected to a fixed number of closest neighbors, ensuring that each layer retains a navigable small-world network property. In the **query** process, the search begins by navigating down from the top layer, leveraging the hierarchical small-world structure to efficiently converge on the region closest to the query point. Once reaching the base layer, the algorithm navigates precisely through the neighborhood graph to identify the approximate nearest neighbors to the query point.

Other AKNN Algorithms. Other AKNN algorithms include tree-based and hash-based methods, among others. Tree-based methods

³The number k of clusters in k -means algorithm and the number K of neighbors in KNN do not need to match.

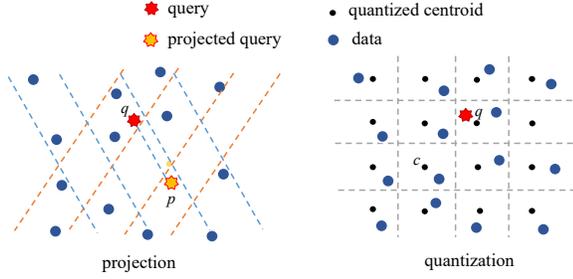

Figure 3: Example of random projection and quantization

identify candidate points through tree routing, while hash-based methods generate candidate points through hash codes, then further identify the result points as AKNN. It is important to note that in practice, these methods are not more appealing than the Inverted File- and graph-based methods due to performance.

2.2 Existing Distance Computation Methods

From the introduction of AKNN algorithms, it is clear that although these algorithms use different approaches to obtain AKNN, they all follow the same candidate generation-verification framework in the query process: In the candidate generation phase, the AKNN algorithms collect a superset of points in S as candidates. In the verification phase, they identify the top- K closest points to a query point q from the candidates as the result to be returned. Note that the methods for generating candidate points differ significantly and thus form different categories of AKNN algorithms, e.g., IVF uses clustering, while HNSW uses traversal to find candidates. However, the verification phase of generating result points from the candidates is actually the same for different AKNN algorithms.

The Verification Phase. To find the K result points from the candidates, current AKNN Algorithms often maintain a set of points using a queue Q (usually organized as a max-heap). They examine each candidate point sequentially; for each candidate point p , they check whether its distance to the query vertex q is not greater than the maximum threshold τ recorded in Q . If so, the new candidate p is inserted into Q and Q is updated; otherwise, p is ignored.

Approximate Distance Computation. The time to compute distances dominates the runtime of the AKNN search, accounting for 80% of the time complexity in IVF and 90% in HNSW. To improve efficiency, an intuitive idea is to use approximate distances instead of exact distances for the verification phase of the AKNN search. Existing work has proposed two methods for computing approximate distances: projection and product quantization (see Fig. 3). Recall that computing distances by successively scanning dimensions leads to a linear time cost in the dimensionality D of the dataset S , these two methods use different approaches to reduce the dimensionality of the data to improve efficiency, and each method has its own appropriate application scenarios.

Projection. Projection methods (such as PCA) map high-dimensional data to a lower-dimensional space, mitigating the curse of dimensionality and facilitating efficient data processing and storage. Specifically, we generally achieve dimensionality reduction by multiplying the vectors in the original space by an orthogonal projection matrix. The advantage of projection methods is that

they are relatively easy to implement, involving the construction of projection matrices for matrix multiplication, and allow for the processing of large, high-dimensional data sets in a comparatively short amount of time.

Product Quantization. Product quantization methods (such as OPQ [22]) are widely used for dimensionality reduction and efficient similarity search in large databases, especially for high-dimensional data. Unlike projection-based methods, which transform data into a lower-dimensional space through the projection matrix. Product quantization takes a different approach, decomposing the high-dimensional space into a Cartesian product of lower-dimensional subspaces. The original high-dimensional vectors are then represented by a combination of quantized vectors from these subspaces. The advantages of product quantization over projection include: • Storage efficiency. product quantization represents high-dimensional data using a combination of indices from its quantized subspaces, which often requires less memory than storage with projection-based methods; • Computational Speed. Due to its quantized nature and the use of a codebook, product quantization can speed up the distance lookup search process, making it effective for distance computing.

Remark. Both the projection and product quantization methods can accelerate the computation of distances. However, employing approximate distances as direct substitutes for exact distances in the verification phase of the ANN algorithms may result in decreased search accuracy. To explain, suppose that $K = 1$ and we want to find the nearest neighbor of a query point q . If the approximate distance of some candidate point p to query q is less than the approximate distance of q 's nearest neighbor, the AKNN algorithm cannot return an exact result.

3 PROBLEM ANALYSIS

To mitigate the loss of accuracy associated with the direct integration of approximate distances into existing AKNN algorithms, ADSampling has been proposed to optimize distance computations. The core idea of the ADSampling method is to use not only approximate distances but also an error bound for the adjustment. By using an error bound, ADSampling can effectively determine whether the current approximate distance is sufficient for the verification phase of the AKNN search. If not, then performing more precise distance calculations can compensate for the inadequacy of the approximate distances. In particular, the introduction of additional accurate calculations allows ADSampling to prevent loss of accuracy.

Approximate Distance. ADSampling uses the random projection distance as the approximate distance. The relation between the random projection distance dis' and the original distance dis can be bounded by the following lemma:

LEMMA 1. For a given object $\mathbf{x} \in \mathbb{R}^D$ a random projection $P \in \mathbb{R}^{d \times D}$ preserves its Euclidean norm with a multiplicative error ϵ bound with the probability of.

$$\mathbb{P} \left\{ \left| \sqrt{\frac{D}{d}} \|P\mathbf{x}\| - \|\mathbf{x}\| \right| \leq \epsilon \|\mathbf{x}\| \right\} \geq 1 - 2e^{-c_0 d \epsilon^2} \quad (1)$$

Error Bound. From Lemma 1, the *error bound* between the approximate distance dis' and the exact distance dis is bounded by $\epsilon \cdot dis$ with a small error probability ($2 \exp(-c_0 d \epsilon^2)$).

How ADSampling Works. ADSampling can be incorporated into any AKNN algorithm. Specifically, in the verification phase of an AKNN algorithm, ADSampling proposes a hypothesis testing framework based on the distance bound above that is designed to address the problem of using the approximate distance directly. That is, if $dis' > (1 + \epsilon) \cdot \tau$, where τ is the maximum distance (threshold) of a queue Q , ADSampling concludes with sufficient confidence that $dis > \tau$ under a preset significance $p = 2 \exp(-c_0 \epsilon_0^2)$, where ϵ_0 is a parameter to be tuned empirically. In this case, it is sufficient to use the approximate distance. Otherwise, the approximate distance is not sufficient to determine whether a point should be included in the quorum Q . We can sample more dimensions and compute a more precise approximate distance to conclude $dis > \tau$ or $dis \leq \tau$.

Limitations. ADSampling has two limitations. (1) ADSampling uses random projection to compute the approximate distance. However, in projection methods, a random projection matrix cannot guarantee that the error between the approximate and exact distances will be minimized. This raises the possibility that the approximate distances computed using a random projection matrix may differ significantly from the exact distances. Note that ADSampling requires incremental approximate distance calculations until the current (approximate) distance can ensure whether or not a candidate point is ignored during the verification phase of the AKNN search. Consequently, improving the accuracy of the approximate distance estimation may allow ADSampling to stop calculating distances for a candidate point sooner, thus speeding up the calculation process. (2) The error bound provided by Lemma 1 is only applicable when the projection matrix is random and thus lacks a more general framework to adapt to more efficient approximate distances such as quantized distance.

4 AN IMPROVED PROJECTION-BASED DISTANCE COMPUTATION METHOD

This section primarily addresses the first problem with ADSampling: the inaccuracy of the approximate distance estimation. We also propose the use of more informative error quantiles to replace error bounds (used in ADSampling), thereby ensuring earlier termination of (incremental) distance computations when verifying a candidate point. Our discussion in this section assumes the use of projection methods to obtain approximate distances, and we will explore the use of more general methods to obtain approximate distances in the following section.

4.1 Accurate Approximate Projection Distance

We investigate the projection matrices that yield approximate distances closely aligned with the true distances under projection methods. By decomposing the approximate (projected) distances, we find that PCA projection matrices produce the optimal approximate distances.

Probabilistic Model and Project Distance. Suppose the \mathbf{x}, \mathbf{q} is the D -dimension database vector and the query vector. We can view these vectors in a transformed coordinate system that is only

an orthonormal matrix away. We denote the transformed (aka, rotated) vectors \mathbf{x}_D and \mathbf{q}_D , respectively. Then we consider a simple model in which we randomly sample data points x from the dataset according to a fixed but unknown distribution U . We consider a global rotation parameterized by the matrix \mathbf{R} . The rotated vector $\mathbf{R}\mathbf{x}$ is then decomposed into \mathbf{x}_d and \mathbf{x}_r . In this new coordinate system, we group dimensions into two groups: those consisting of the first d dimensions and the rest. Then we can denote \mathbf{x}_D as $(\mathbf{x}_d, \mathbf{x}_r)$, where \mathbf{x}_d is \mathbf{x}_D truncated to the first d dimensions and \mathbf{x}_r the rest. Similarly, $\mathbf{q}_D = (\mathbf{q}_d, \mathbf{q}_r)$.

The square Euclidean distance can be computed by

$$\begin{aligned} \|\mathbf{x} - \mathbf{q}\|^2 &= \|\mathbf{x}_D - \mathbf{q}_D\|^2 = \|\mathbf{x}\|^2 + \|\mathbf{q}\|^2 - 2 \cdot \langle \mathbf{q}, \mathbf{x} \rangle \\ &= \|\mathbf{x}_d\|^2 + \|\mathbf{q}_d\|^2 + \|\mathbf{x}_r\|^2 + \|\mathbf{q}_r\|^2 \quad (2) \\ &\quad - 2 \cdot (\langle \mathbf{q}_d, \mathbf{x}_d \rangle + \langle \mathbf{q}_r, \mathbf{x}_r \rangle). \end{aligned}$$

Note that $\|\mathbf{x}_d\|^2 + \|\mathbf{x}_r\|^2$ can be precomputed offline. The $\|\mathbf{q}_d\| + \|\mathbf{q}_r\|^2$ only needs to be computed once for a given query. Let $C_1 := \|\mathbf{x}_d\|^2 + \|\mathbf{q}_d\|^2 + \|\mathbf{x}_r\|^2 + \|\mathbf{q}_r\|^2$ and $C_2 := \langle \mathbf{q}_d, \mathbf{x}_d \rangle$ (whose computation cost during the query processing is $O(d)$). The approximate distance can be computed as $dis' = C_1 - C_2$ and the error term compared to the precise distance is $-2 \cdot \langle \mathbf{q}_r, \mathbf{x}_r \rangle$.

Minimize Residual Variance. We can derive a concentrated inequality for pruning precise distance computations based on the variance of error terms and the well-known Chebyshev's inequality.

Initially, we address the computation of the variance associated with the error term. Let σ_i^2 represent the variance of the i -th dimension in distribution U . Upon receiving a query, the variance of the inner product for the residual dimension is $\sigma_i^2 q_i^2$. In the case where we use orthogonal projection, the covariance of each dimension after rotation (rotate) is zero. Consequently, the variance of the error term is computed as:

$$Var(-2 \cdot \langle \mathbf{q}_r, \mathbf{x}_r \rangle) = 4 \cdot \sum_{i=d+1}^{i \leq D} (\mathbf{q}_i \sigma_i)^2$$

Following this, we explore all orthogonal projection matrices to reduce the variance of the error term and we get the following theorem 1.

THEOREM 1. *For a given vector dataset S , the PCA projection matrix maximizes the projected dimension variance which also minimizes the residual dimension variance.*

The PCA projection matrix is well-suited to address our problem, where the PCA projection maximizes the projection variance. We show that the PCA also minimized the variance in residual dimension. We investigate the distribution of error terms on real datasets and the differences among various projection matrices. For the DEEP1M dataset (256 dimensions) and a given query \mathbf{q} , we plot the distribution of $\langle \mathbf{q}_r, \mathbf{x}_r \rangle$. As illustrated in Fig. 4a, with a residual dimension of 128, the PCA projection matrix demonstrates a more concentrated distribution compared to the random projection. Furthermore, as shown in Fig. 4b, with increasing projection dimensions and decreasing residual dimensions, the error gradually converges to 0. Then we study the error bound of the projection distance error.

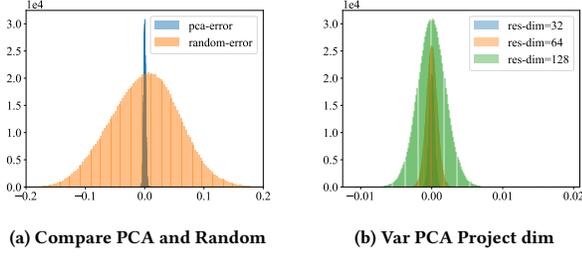

Figure 4: Example of PCA Error and Random Projection Error Distribution in Deep1M Dataset

4.2 More Informative Error Quantiles

Inspired by the role of error bounds in ADSampling, we introduce the concept of error quantiles. Compared to error bound, error quantiles contain more information, thus more likely to enable early determination whether a candidate point can be disregarded in the verification phase of AKNN search.

Base on the project distance decomposition we can get the following deterministic inequality

$$\|\mathbf{x}_D - \mathbf{q}_D\|^2 = C_1 - C_2 - 2 \cdot \langle \mathbf{q}_r, \mathbf{x}_r \rangle \geq C_1 - C_2 - 2 \cdot \|\mathbf{q}_r\| \cdot \|\mathbf{x}_r\| \quad (3)$$

The inequality is due to the Cauchy–Schwarz inequality, where

$$\langle \mathbf{q}_r, \mathbf{x}_r \rangle \leq \|\mathbf{q}_r\| \cdot \|\mathbf{x}_r\|$$

Remark. In fact, we can also apply the Hölder’s Inequality, which states that for p and q such that $\frac{1}{p} + \frac{1}{q} = 1$.

Therefore, we have two choices:

- We can use the RHS of Equation (3) to prune candidates using $O(d)$ cost spent mainly to compute $\langle \mathbf{q}_d, \mathbf{x}_d \rangle$ (assuming the offline precomputed and loaded $\|\mathbf{x}_r\|$ and $\|\mathbf{x}_d\|$, on-the-fly and computed-once $\|\mathbf{q}_d\|$ and $\|\mathbf{q}_r\|$).

- Or, we can leverage a concentration inequality to prune the distance computation, akin to our focus on approximate nearest neighbor search.

Error Distribution. The Cauchy–Schwarz inequality achieves no false negative inequality. As we focus on the **approximate** nearest neighbor search, we can do better with the study of the distribution of the error which we set as $\epsilon = dis' - dis$. With $O(d)$ computation, the approximate distance $dis' = C_1 - C_2$, the precise distance $dis = C_1 - C_2 - 2 \cdot \langle \mathbf{q}_r, \mathbf{x}_r \rangle$ and the error $\epsilon = 2 \cdot \langle \mathbf{q}_r, \mathbf{x}_r \rangle$. For C_1 part, The $\|\mathbf{x}_d\|^2 + \|\mathbf{x}_r\|^2$ can precompute and store, the $\|\mathbf{q}_d\|^2 + \|\mathbf{q}_r\|^2$ only need compute once for a single query. Remaining the C_2 part for $O(d)$ cost. As we mentioned before, we can leverage the variance of the error $\sigma_\epsilon^2 = Var(-2 \cdot \langle \mathbf{q}_r, \mathbf{x}_r \rangle)$ and Chebyshev’s inequality⁴ to obtain a bound and utilize it to prune distance calculations as below:

$$P(|-2 \cdot \langle \mathbf{q}_r, \mathbf{x}_r \rangle| \geq k\sigma_\epsilon) \leq \frac{1}{k^2}$$

Or we can do better with the Gaussian distribution assumption.

Error Quantiles. Assume that the data follow the Gaussian distribution $\mathbf{x} \sim \mathcal{N}(0, \Sigma)$. When query \mathbf{q} is given, the distribution of error can be regarded as a linear accumulation of multiple Gaussian distributions. Consider the error item $\epsilon = -2 \cdot \langle \mathbf{q}_r, \mathbf{x}_r \rangle$ in Equation 2 of the $O(d)$ time complexity compute projection distance in

⁴We centralized the data to yield a mean of zero.

Algorithm 1: BSA_{res} algorithm

Input: Threshold τ , Multiplier m , Project dim d , Transformed query \mathbf{q} , Transformed data \mathbf{x}

Output: Result: 0 with precise distance dis or 1 with approximate distance dis'

```

1  $C_1 \leftarrow \|\mathbf{x}\|^2 + \|\mathbf{q}\|^2$ ; // Precompute Once For Single Query
2  $C_2 \leftarrow 2 \cdot \langle \mathbf{x}_d, \mathbf{q}_d \rangle$ ; // Compute On the Fly
3  $\sigma_r \leftarrow \sqrt{4 \cdot \langle \mathbf{q}_r^2, \sigma_r^2 \rangle}$ ; // Precompute Once For Single Query
4 if  $C_1 - C_2 - m \cdot \sigma_r > \tau$  then
5   return 1 with  $dis' = (C_1 - C_2)$ ;
6 else
7    $C_3 \leftarrow 2 \cdot \langle \mathbf{x}_r, \mathbf{q}_r \rangle$ ; // Compute On the Fly

```

a d -dimensional space. Since \mathbf{x} follows a zero mean, then for each dimension $x_i \sim \mathcal{N}(0, (\mathbf{q}_i \sigma_i)^2)$ where σ_i is the standard deviation in each dimension. Then we can get

$$-2 \cdot \langle \mathbf{q}_r, \mathbf{x}_r \rangle \sim \mathcal{N}(0, 4 \cdot \sum_{i=d+1}^{i \leq D} (\mathbf{q}_i \sigma_i)^2). \quad (4)$$

The variance of error only needs to be computed once for a single query \mathbf{q} . Then we rewrite the distribution as $\epsilon \sim \mathcal{N}(0, \sigma^2)$. From the empirical rule of Gaussian distribution, 99.7% of the values lie three standard deviations from the mean, which we can obtain an error quantile based on the accumulation of standard deviation ($3 \cdot \sigma$ for 99.7% quantile).

4.3 Implementaion

We then explore the integration of the projection method and the error quantiles into current AKNN algorithms, for utilization in the search process.

Deriving Data Distribution from Training Data. To minimize the residual dimension error and obtain the standard deviation of the error from the data distribution. We utilize training data with the same distribution to the queries for the generation of data distribution. Based on this distribution, we perform PCA projection and estimate the standard deviation of the residual dimensions. To get the distance bound, we employ the approximate distance $dis' = C_1 - C_2$ minus m times the error standard deviation, resulting in a high probability that the precise distance will be greater than the distance bound within the training data generate distribution. The entire process of BSA_{res} is summarized in Algorithm 1. For the problem that the distribution of data changes under different search parameters, we perform PCA on the dataset points as an approximation. For the standard deviation, we can consider the KNN distribution of the query, because it will not change with the search parameters and directly affects search accuracy.

Incremental Computation. A significant advantage of projection methods lies in the capability to compute the projection dimensions incrementally to achieve a more accurate approximation of distance up until the exact distance. Similar to ADSampling where sample projection dimensions are progressively increased BSA_{res} also supports the incremental addition of computational dimensions. Specifically, for the current approximate distance dis' , if BSA_{res} prunes

Algorithm 2: Incremental-BSA_{res}

7     return 1 with  $dis' = (C_1 - C_2)$ ;
8   else
9      $d \leftarrow d + \Delta_d$ ;
```

the computation of the exact distance for the current point, the computation halts. Conversely, if BSA_{res} does not prune the precise distance computation for the current point, the computation proceeds by incrementally adding dimensions. Subsequently, the new approximate distance is utilized to continue pruning the precise computation until the accumulated dimensions reach the original dimensionality or it is pruned and stopped earlier. We summarize the method of using incremental BSA_{res} in Algorithm 2.

5 A GENERAL DISTANCE COMPUTATION METHOD

This section mainly addresses the lack of generality associated with ADSampling. Follow the same idea as from BSA_{res} of using training data to get a distance quantile for pruning the distance computation. We propose the quantile-driven framework that BSA_{res} can be regarded as an instance of it. Building on this foundation, we propose a learning-based approach as a new instance that is applicable to various approximate distances and offers parameter selection tailored to different AKNN search precision requirements. Note that our method does not impose any requirements on how to obtain approximate distances, which allows for broader applicability compared to ADSampling.

5.1 Quantile-Driven Framework

We encapsulate the core idea of the BSA_{res} algorithm in Section 4 within a quantile-driven framework. The essence of this approach lies in leveraging a training set that shares the distribution with the queries to obtain the error distribution of approximate distances during the querying process. Subsequently, the approximate distance minus the upper quantile of the error is used as the distance bound to prune distance computations. We summarize it as the BSA framework, as shown in Figure 5.

The BSA framework is utilized to determine the distribution of this error by calculating both the precise and approximate distances. Training data with a distribution analogous to the query is used to generate the search data distribution. To determine the error quantile, the BSA_{res} instance uses the multiplier and the standard deviation of the error to get the error quantile ϵ_q . Given the error quantile ϵ_q , the inequality $dis > dis' - \epsilon_q$ ensures a manageable

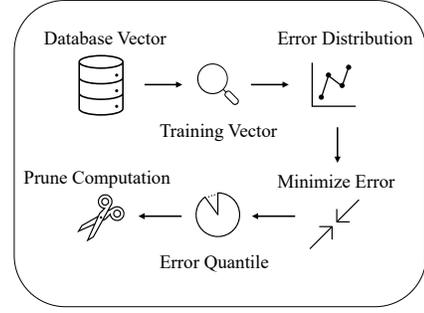

Figure 5: The Process of Quantile-Driven Framework

probability of error occurrence in the training data. Thus, the criterion $dis' - \epsilon_q > \tau$ can be utilized to determine whether reliance on the approximate distance is adequate or if a precise distance computation is required.

5.2 A Learning-Based Instance

The BSA_{res} approach aims to minimize the error quantile, thereby improving the query efficiency. However, the BSA_{res} approach cannot be easily adjusted to other approximate distances, since it is difficult to guarantee that the error follows the Gaussian distribution. Meanwhile, BSA_{res} still needs to manually set the standard deviation multiplier to meet the AKNN’s accuracy requirement. Therefore, in this section, our objective is to solve these two problems with the learned-based method, which can easily *adapt to any approximate distance* and provide *auto parameter configuration* for any search accuracy requirement.

For the generation of training data, we still follow the same process as with the BSA_{res} instance, but since we consider arbitrary approximate distances, we cannot rely solely on projection methods to minimize error. Instead, we use a linear model to replace the minimization of errors. Specifically, we use features related to the approximate distance to reconstruct the precise distance, achieving higher pruning efficiency. To achieve an efficient classifier, we use the **approximate distance** dis' and the **threshold** τ as **features**, and then we learn the weight of two features and the intercept that can be used to classify whether dis is greater than τ . The linear model can be written as:

$$\begin{aligned} L &= \text{sign}(w_1 dis' + w_2 \tau + b > 0) \\ &= \text{sign}(m_1 dis' + \beta > \tau) \end{aligned}$$

where Label 0: $dis \leq \tau$ and Label 1: $dis > \tau$. We employ a straightforward linear model with Binary Cross-Entropy (BCE) as the loss function to implement our model. From our practical experiments and experience, using BCE as the reconstruction loss results in a more stable performance compared to other linear reconstruction methods, such as using Least Squares to minimize the MSE (Mean Squared Error) of distance approximation.

With the reconstruction distance $m_1 dis' + \beta$, we can use the numerical method such as binary search for the intercept term β' (work same as error quantile) to ensure $dis > m_1 dis' + \beta'$ with a manageable small failure probability. However, the failure probability of equation $dis > m_1 dis' + \beta'$ cannot directly affect search accuracy. We are expected to obtain the β' corresponding to the recall target for a specific AKNN search accuracy. As we take the

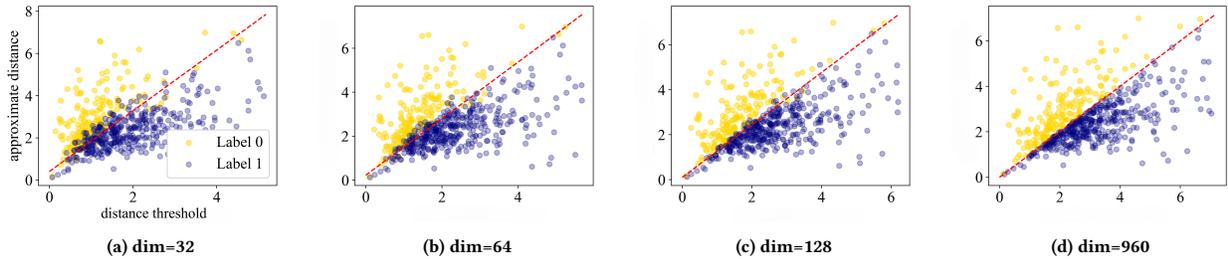

Figure 6: Example of Linear Models with PCA as Approximate Distance

BCE as the loss function, we can set the threshold τ as the k -NN distance of query where Label 0 data becomes the KNN of query. Then we can binary search β' to ensure that the learned instance achieves the target recall r on Label 0 in the training dataset to achieve auto parameter configuration.

Remark. The learning-based instance is comparable to the BSA_{res} approach of Section 4 by taking $m_1 = 1$ and $\beta = m \cdot \sigma$. The difference is that the learned-based method is capable of any approximate distance which is more general.

5.3 Implementation

Approximate Distance and Feature Select. For projection-based approximate distance, we use the simple PCA projection as the approximate distance without taking the decomposition by Equation 2 for the general case denoted as BSA_{pca} . For another popular approximate method, the product quantization distance, we utilize the distance to quantized centroids of the query q to the database point u known as the Asymmetric Distance Computation (ADC), as the approximate distance dis' . Following the same idea as PCA, we use OPQ [14] as our final quantized approximate distance method, which also uses an orthogonal matrix to rotate the space for a more precise approximate distance and denote as BSA_{opq} . More accurate quantification methods, such as AQ [2], CompQ [36], LSQ [30], and other additional quantification methods are no longer within the scope of our consideration due to their low efficiency of the lookup table. For quantization methods, we can also utilize the distance from u itself to the quantized centroid as an **additional feature**. This multi-feature approach can further enhance the effectiveness of the linear model. Moreover, we noticed that product quantization has different optimizations with different hardware environments. In our experiments, we additionally analyzed the inference efficiency of using the PQ-scan[1] as an approximate distance with the SIMD-SSE instruction.

Multiple Linear Model. We can also use multiple linear models with the same idea in ADSampling or Algorithm 2, denoted as L_1, \dots, L_n , each corresponding to a unique projection dimension as shown in figure 6, with an associated error probability e_1, \dots, e_n on Label 0 classification. If the dis' for the current projection dimension is classified as Label 0 by the current linear model L_i , we continue to increase the projection dimension. This process continues until the project dimension equals the original dimension, at which point we obtain an accurate distance. If this distance is less than the threshold τ , we update the result queue.

To achieve the target recall r for Label 0, we need to consider the number of false positives (FP) for each linear model. A straightforward strategy is to set the recall target for each of the n linear models as $r_i = (1 - (1 - r)/n)$. This approach ensures that the overall recall target still satisfies the recall constraint for label 0. With the same idea as ADSampling, we also set a corresponding classifier L_i for every Δ_d dimension. At the same time, the target recall for each classifier is set as $r_i = (1 - (1 - r)/(D/\Delta_d))$. If the current classifier result is 0, we continue to calculate the projection distance and use the next classifier until the exact distance is computed. Otherwise, we prune this candidate. It is worth noting that we do not use multiple linear classifiers with BSA_{opq} . This is because of the use case of SIMD Instruction, which computes 4 or 8 quantized distances in one operation. Early stopping of one quantized distance will not improve performance unless all quantized distances stop early.

6 TIME AND SPACE ANALYSIS

6.1 Projection Distance

We first study the time complexity of the BSA_{res} and BSA_{pca} based on the PCA projection. For the case without incremental computation, the expected time complexity of a single inference is highly dependent on the pruning rate, the ratio of the pruned cases to all distance comparison operations. For PCA as an approximate distance, as the projection dimension is d and the pruning rate η with the corresponding BSA_{pca} instance. The expected time complexity of a single inference is $O(d \cdot \eta + (D - d) \cdot (1 - \eta))$. Another benefit of the projection distance is that the project process can be regarded as rotating the space, and we can continue to add dimensions until we obtain the precise distance. This approach does not require extra space usage and reuses the approximate distance, potentially enhancing efficiency. The BSA_{res} and BSA_{pca} methods introduce additional time for rotating the space. For a single query, we require a time complexity of $O(D^2)$ to perform matrix multiplication to project (rotate) the query. Furthermore, for the BSA_{res} method, we incur an extra time cost of $O(D)$ to calculate the variance of the residual dimension by accumulating the product of the variance of each dimension and the corresponding query dimension. We also need $O(D)$ time to compute the square sum of query q . For the BSA_{res} method, we further require an additional $O(n)$ space to store the square of the square sum of each vector.

Then we consider the multi-linear model with the PCA method. Assume that we have m linear models with every $\Delta_d \cdot m = D$ for each linear model. The pruning rate for each linear model is

Table 2: Dataset Statistics

Dataset	Dimension	Size	Query Size
SIFT	128	10,000,000	1000
GIST	960	1,000,000	1000
DEEP	256	1,000,000	1000
GLOVE	300	2,196,017	1000
TINY5M	384	5,000,000	1000
WORD2VEC	300	1,000,000	1000

denoted by η_1, \dots, η_m . Then the expected time complexity for a single inference is the following.

$$O\left(\sum_{i \leq m} i \cdot \Delta_d \cdot \prod_{j < i} (1 - \eta_j) \cdot \eta_i\right)$$

Calculating the above time complexity can also be regarded as calculating the average scan dimension.

6.2 Quantization Distance

For the quantization method, as OPQ in our approach, the additional time cost consists of both the query rotation $O(D^2)$ and the construction of a lookup table. With OPQ implemented across m subspaces, each containing 2^{nbit} quantized centroid, the time complexity of constructing a look-up table is $O(D \cdot 2^{nbit})$. With the look-up table, the calculation of the asymmetric distance requires only m times the look-up from the table. Unlike the projection method, the quantized-based approach needs to recompute the distance if it cannot prune the precise distance computation, rather than increment the cumulative dimension. With the linear model L and the pruning rate η_q , the expected time complexity for single inference is $O(m + (1 - \eta_q) \cdot D)$. The features of the linear model L are the approximate distance, the point-to-centroid distance, and the threshold. Differing from the projection-based method, the use of quantization brings extra space costs. Considering quantization across m subspaces, the extra space cost requires $n \cdot m \cdot nbit$ bits. Where the m is usually taken as 1/4 or 1/8 of origin dimension D and the extra space cost is from 1/32 to 1/64 of the dataset’s size when using 32-bit float vectors.

7 EXPERIMENTS

7.1 Experimental Settings

Datasets. We employ six publicly available datasets of different sizes and dimensionalities, as outlined in Table 2. These datasets have been extensively utilized as benchmarks for evaluating AKNN search algorithms. It is important to note that these publicly available datasets encompass base vectors and query vectors. For datasets that provide learning data, such as GIST and DEEP, we directly utilize the provided learning data. However, for datasets that do not provide learning data, we randomly sample 100,000 instances from the base data to train the linear model and then remove them from the base data. Note that all vector data in the experiment are stored in float32 format.

Performance Evaluation. We employ recall as a metric, quantifying the ratio of successfully retrieved ground truth k -nearest neighbors to the total number of k neighbors. To gauge efficiency, we utilize query-per-second (QPS), which measures the number of queries processed per second, including the end-to-end query time, product quantization codebook calculation time, and encompassing random transformations on query vectors. Additionally, we evaluate the total number of dimensions scanned by random projection and PCA. For OPQ we use the pruning rate to evaluate the efficiency. All the metrics mentioned are averaged over the entire query set.

Compare Method. We list the compared method below:

- HNSW: HNSW with all precise distances computed.
- HNSW++: HNSW with ADSampling method.
- HNSW-BSA_{opq}: HNSW takes OPQ as the approximate distance for the learned instance approach.
- HNSW-BSA_{pca}: HNSW takes PCA as the approximate distance for the learned instance approach.
- HNSW-BSA_{res}: HNSW takes residual dimension variance for pruning.
- IVF: IVF with all precise distances computed.
- IVF++: IVF with ADSampling method.
- IVF-BSA_{opq}: IVF takes OPQ as the approximate distance for the learned instance approach.
- IVF-BSA_{pca}: IVF takes PCA as the approximate distance for the learned instance approach.
- IVF-BSA_{res}: IVF takes residual dimension variance for pruning.

Training Configuration. For the training of the linear models, we directly take the KNN of learning data as label 0. For data with label 1, we treat the learning data as the query and generate training data by recording the visited points and eliminating the KNN(label 0). For all training items, we compute their approximate distance, threshold, and other features to train the linear classifier with BCE as the loss. Specifically, we use 10,000 learning vector data for each dataset as training queries and perform the search algorithm with a fixed configuration to get the training data. For the search parameters used to generate label 1 data, we empirically tune it so that it can generate enough label 1 data. Our experiments also show that, as long as the scale of label 1 is sufficient, the model demonstrates good generalization across different search parameters. We set the recall target r as 0.995 for the time-accuracy tradeoff experiment and provide a verified recall target experiment as follows.

Index Configuration. We mainly consider the index construction of two AKNN algorithms, HNSW, and IVF. For HNSW, two key parameters control the graph construction: M determines the number of connected neighbors, and $efConstruction$ controls the quality of the approximate nearest neighbors. Following the original HNSW work, we set $M = 16$ and $efConstruction = 500$. For IVF, as recommended in the Faiss library, the number of clusters should be around the square root of the database size. We set the number of clusters to 4,096 as in ADSampling. All C++ code compiles with g++ 11.4.0 and -O3 optimization. Python code (used in indexing and training for linear models, PCA, and OPQ) runs on Python 3.8. Experiments use an Intel(R) Xeon(R) Platinum 8352V

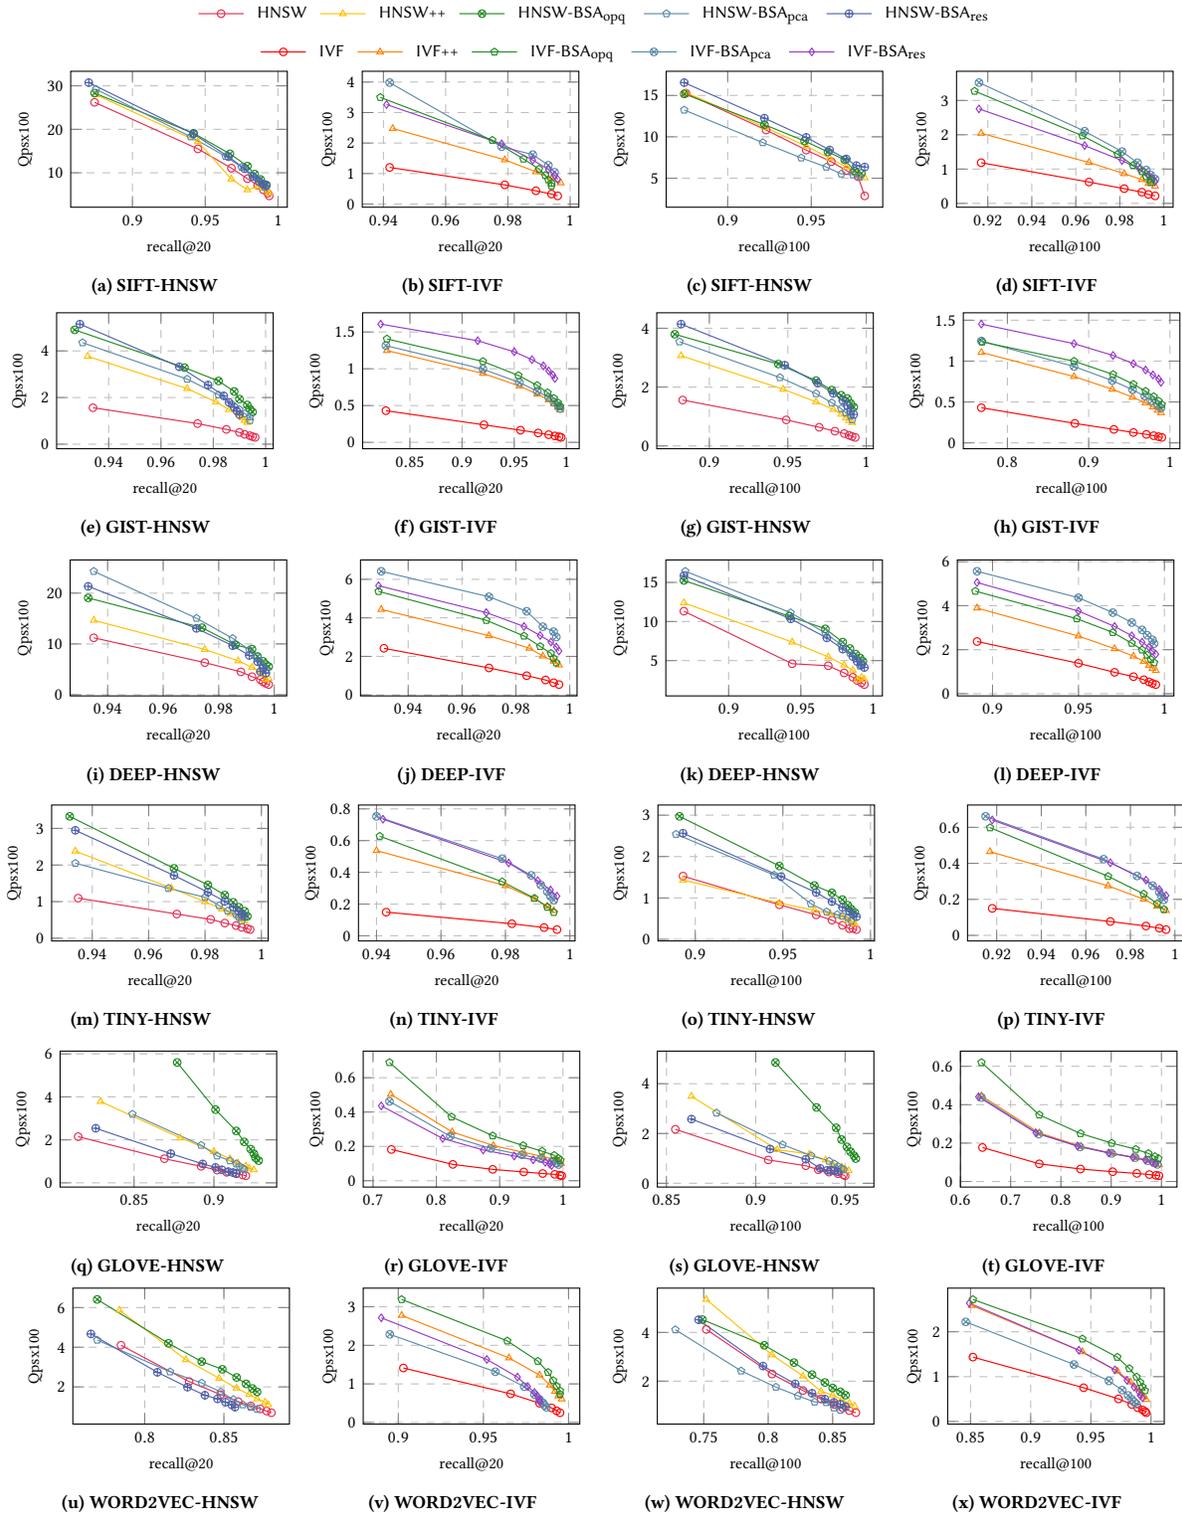

Figure 7: Time-Accuracy Tradeoff and Dimensionality (HNSW and IVF)

CPU @ 2.10GHz with 512GB memory, running in Ubuntu Linux. We present results with SSE in [35] due to space limit.

Approximate Distance Configuration. For the random projection approach, we set $\epsilon_0 = 2.1$ and $\Delta_d = 32$ which is recommended as the best performance in ADSampling. For the PCA approach, we also set every $\Delta_d = 32$ dimension to construct a linear model to achieve the same condition as ADSampling. For the OPQ approach, we set the subspace number as $d/8$ for the GIST dataset and $d/4$ for the others since all the dimensions of the dataset can be divided by 4. The features used for the PCA approach are the project distance(approximate distance) and the threshold. For the OPQ approach, we added an additional point-to-centroid distance as a feature. The target recall is set as 0.995 for the BSA_{pca} and BSA_{opq} methods. For the multiplier m for BSA_{res}, we set it as 8 for SIFT, GIST, and DEEP, 12 for TINY and WORD2VEC, and 16 for the GLOVE dataset. For the case of multiple classifiers, we set the target recall for each classifier based on Δ_d as $r_i = (1 - (1 - r)/(D/\Delta_d))$.

7.2 Experimental Results

Overall Results. We plot the time accuracy curve with two popular algorithms HNSW and IVF which the upper right is better. We denote that the method HNSW++ is the ADSampling method with the k -size result queue threshold as illustrated in the figure 7. We use HNSW-BSA_{res}, HNSW-BSA_{pca} and HNSW-BSA_{opq} to represent the HNSW with a residual-based classifier, a learned-based classifier with PCA and OPQ as an approximate distance feature. We also adapt the split result queue strategy in HNSW++. The IVF++ denotes the ADSampling method with cache level optimization, and IVF-BSA_{pca} represents the PCA approximate method with the same optimization as IVF++. The IVF-BSA_{opq} method represents the OPQ approximate method without any cache-level optimization, but we provide experiments with SIMD instructors implemented in the Appendix.

To achieve the tradeoff between time-accuracy, we varying N^{ef} for HNSW, HNSW++, HNSW-BSA_{opq}, HNSW-BSA_{pca}, HNSW-BSA_{res} and N^{probe} for IVF, IVF++, IVF-BSA_{opq}, IVF-BSA_{pca}, IVF-BSA_{res}. As the focus of our approach, we consider the high recall(> 85%) as the main scenario that the approximate distance methods without fast inference cannot achieve. We observe the following results. (1) From the overall experimental result, the fast inference method can achieve a large margin speed-up with the IVF-based method in which DCOs constitute the main time cost. (2) For the WORD2VEC dataset with the HNSW method, the recall reaches a bottleneck at 85%(caused by outdegree limitation of HNSW) and the performance of all fast inference methods including ADSampling has a significant discrepancy compared with other datasets. For HNSW+, IVF+, and PDSampling methods proposed by ADSampling, that is, methods that do not use split queues, memory layout optimization, and the incremental distance calculation with the threshold. The performance of the above methods has a significant gap compared to HNSW++ and IVF++, which are no longer considered in our experiment.

Results of Verified Target Recall. We study the parameter of target recall with different approximate methods. As we mentioned in the preliminary, the actual threshold is greater than the threshold

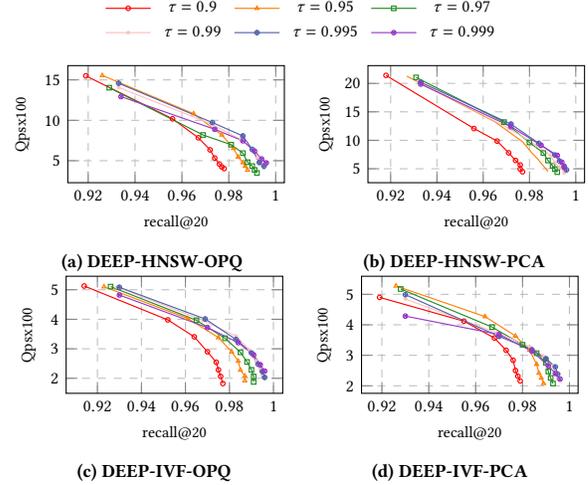

Figure 8: Parameter Study on Target Recall τ

N^{ef}	Proj	PCA	OPQ
500	6.0%	8.9%	12% + 5.9%
1000	3.9%	5.6%	7.6% + 3.8%
1500	3.0%	3.1%	5.8% + 2.9%
2000	2.5%	2.9%	4.7% + 2.3%

Table 3: Extra Time Ratio on GIST-HNSW

for training. Therefore, target recall is the expected lower bound on training data. The overall performance of the recall will be better than the target recall since the update threshold will be larger than the ground truth threshold (we take the current threshold as the feature for inference). Moreover, for multiple linear models, we use the same strategy as union-bound, which will also make the test recall higher than the target. As in the parameter study of r in Fig. 8, we found that in the case of $r = 0.995$, the search algorithm of both IVF and HNSW can achieve the best tradeoff between efficiency and recall loss (less than 0.5%) which is selected as the default target recall.

Results of Extra Time. A common aspect of ADSampling and our approach is the transformation of vector data, which incurs additional time costs. Upon receiving a query, the search algorithm first executes the transformation, and its cost can be amortized by all the distance computations involved in answering the same query. We implement this process via a matrix multiplication operation (with C++ Eigen Library), which takes $O(D^2)$ time and 0.344ms with GIST data. Moreover, the OPQ inference requires additional time cost for the computation of the look-up table, which takes $O(2^{nbit} \cdot D)$ time and can be considered as 2^{nbit} times (usually 256) distance calculation, which takes 0.170ms with GIST data. The ratio between the extra time and the full query time is illustrated in Table 3.

Results of Scan Dimensions. The ADSampling method and the PCA inference method can be evaluated by the scan dimensions

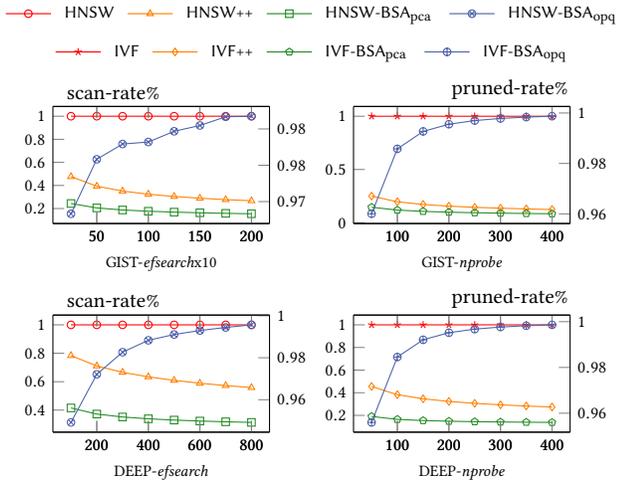

Figure 9: Dimension Scan Rate and Pruned Rate

since the visited point set is the same. We plot the average scan dimension ratio compared with the naive method plot (red line) to the ADSampling method (orange line) and BSA_{pca} method (green line) with the left axis in figure 9. For the BSA_{opq} method, we plot the pruning rate with the right axis and blue line to verify its efficiency. The query performance corresponds to the time-accuracy tradeoff in Figure 7. It can be observed that the ratio of average scan dimension decreased as the search algorithm visited more points (with larger search parameters). With a larger search parameter, the OPQ with 120 subspaces (for the GIST dataset) inference can achieve a near 100% ($\geq 95\%$) pruning rate which means that the case of needed full precise data only consists of a very small portion. This observation can make our approach more suitable to combine with disk-based methods.

Results for Evaluating the Distance Approximation. We then study the method with only approximate distances without error quantile or bound. We take the OPQ with HNSW and IVF algorithms notes as $HNSW_{opq}$ and IVF_{opq} . The approximate distance method with the parameter 120 subspaces for the GIST dataset and 64 subspaces for the DEEP dataset is the same parameters as $HNSW-BSA_{opq}$ and $HNSW-BSA_{pca}$. It can be seen that there is about a 7% to 9% recall gap between the OPQ-only method ($HNSW_{opq}$, IVF_{opq}) to the leaned inference one. The approximate distance with PCA at the same setting will become even worse as the OPQ is more accurate than PCA in various data settings.

8 RELATED WORK

8.1 Existing AKNN Algorithms

Existing methods for accelerating the computation of distances between points/vectors include ADSampling [13] and FINGER [6]. ADSampling relies on the Johnson-Lindenstrauss (JL) lemma [23] to provide a probabilistic bound and uses it to accelerate distance calculations. FINGER [6], on the other hand, is a method applicable solely to graph-based approaches, primarily by estimating angles between neighboring residual vectors during the graph search stage to

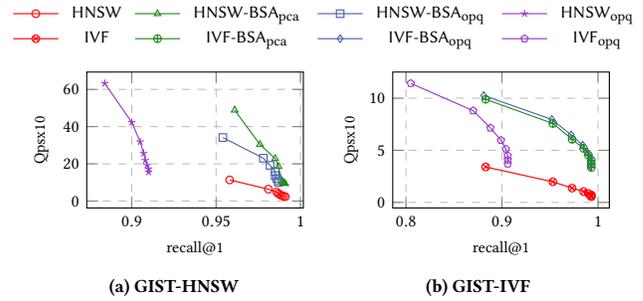

Figure 10: Recall@1 Time-Accuracy Tradeoff

achieve acceleration. FINGER is exclusively applied to graph-based methods and is therefore not included in the baseline comparison.

8.2 Learning-Based Methods for AKNN search

Learning-based methods have made significant contributions to the field of graph-based AKNN search. Notably, several recent studies have leveraged machine learning techniques to enhance different aspects of AKNN search. In particular, [4, 9] have applied learning techniques to predict the next node during graph traversal, enabling more efficient navigation through the search space.

It is important to note that the majority of these learning-based approaches primarily focus on improving the index construction and search processes of AKNN search. They often overlook the critical aspect of distance calculation, which constitutes a significant portion of the overall search time. In contrast, our approach places a strong emphasis on distance computation, enabling seamless integration with the aforementioned methods. By tackling the computational bottlenecks inherent in distance calculations, our method provides a comprehensive solution to boost AKNN search efficiency throughout the search process.

9 CONCLUSION

In this paper, we present an innovative approach that significantly improves both the accuracy and efficiency of AKNN search. Our proposed methodology revolves around decomposing the computation of projection distances, optimizing the projection matrix to minimize error terms, and employing an error quantile to effectively prune unnecessary distance computations. Moreover, through a quantile-driven framework that utilizes learning-based methods and numerical analysis, our approach demonstrates notable improvements in search speed over the current method ADSampling, especially on datasets of different data types and scales.

In addition, it is necessary to consider similarities beyond Euclidean Space. (1) The cosine-based similarity and inner product similarity search on given data and query vectors is equivalent to the Euclidean nearest neighbor search on their normalized data and query vectors. (2) Otherwise we can directly use the corresponding approximate method such as the product quantization in inner product space [16, 17] for quantization distances with relatively low quantization distortion and computation cost. With the more accurate approximate method, our approach can achieve a higher efficiency improvement with the accuracy requirement constraint.
