(Received xx; revised xx; accepted xx)

Settling velocity statistics for dilute, non-Brownian suspensions of polydisperse spheres having a log-normal size distribution are analysed by Stokesian Dynamics, as a function of the total volume fraction and width of the size distribution. Several hundred instantaneous configurations are averaged to obtain reliable statistics. Average velocities for each particle class are compared to the models proposed by Batchelor, Richardson & Zaki, Davis & Gecol, and Masliyah-Lockett-Bassoon (MLB). Batchelor's model is shown to give reasonably accurate predictions when the volume fraction is within 5%. Because of its complexity, this model is however hardly used in practice, so lower-order models are needed. We found that while the other hindered settling models can give reasonably accurate predictions of the velocity of the largest particles, all of them overestimate - in certain cases by a large margin - the velocity of the smaller particles. By computing the fluid-particle velocity slip for each particle class and using Batchelor's model, we explain why predicting the lower tail of the particle size distribution is challenging, and propose possible avenues for model improvement. The analysis of velocity fluctuations suggest quantitative similarities between velocity fluctuations in monodisperse and polydisperse suspensions.

**Key words:** Authors should not enter keywords on the manuscript, as these must be chosen by the author during the online submission process and will then be added during the typesetting process (see Keyword PDF for the full list). Other classifications will be added at the same time.

# 1. Introduction

The prediction of the settling velocity of polydisperse suspensions is crucially important in applications, such as wastewater treatment (He *et al.* 2021), food processing (Wang *et al.* 2020), nanoparticle sorting (Bonaccorso *et al.* 2013), particle size characterisation (Papuga *et al.* 2021), materials recycling (Wolf 2021), and sediment transport modelling (Dorrell & Hogg 2010). Despite decades of research on polydispersed suspension this field still offers

† Email address for correspondence: l.botto@tudelft.nl

Abstract must not spill onto p.2

interesting scientific problems. A central challenge is the prediction of the settling velocity of each particle class in a polydisperse system. This information is crucially important, not only because the velocity of each class dictates the particle concentration profile, but also because only by knowing the velocity of each class it is possible to separate particles by size. The accurate prediction of the class-averaged particle velocity has recently become important because of the need for accurate size fractionation of micro and nanoparticles (Bonaccorso *et al.* 2013; Backes 2016). Furthermore, from the knowledge of the class-averaged particle velocity one can measure the particle size distribution from the time evolution of the concentration profile (Papuga *et al.* 2021), which is the principle underlying the functioning of an analytical centrifuge (Chaturvedi *et al.* 2018). The current work aims to analyse the validity of several models used for the prediction of the class-averaged velocity, comparing against simulation results.

For a Stokesian suspension of polydisperse spheres grouped into *m* distinct particle classes, the average settling velocity of the *i*-th class can be written as  $\langle u_i \rangle = u_{St,i}h_i(\phi)$ , where  $u_{St,i} = \frac{2}{9\mu}a_i^2(\rho_p - \rho_f)g$  is the single-particle Stokes velocity of the *i*-th class,  $h_i(\phi)$  is the hindered settling function of that class, and  $\phi = (\phi_1, \phi_2, ..., \phi_m)$  is the vector of volume fractions (Davis & Acrivos 1985);  $a_i$  is the particle radius,  $\mu$  is the fluid viscosity, and  $\rho_p - \rho_f$  is the density difference between the particles and the fluid. The literature reports several models for  $h_i(\phi)$ , as reviewed by Berres *et al.* (2005).

Batchelor (1982) showed that in the dilute limit the hindered settling function can be written as

$$h_i(\phi) = 1 + \sum_{j=1}^m S_{ij}\phi_j,$$
(1.1)

and using the pair-wise interaction approximation developed analytical solution for the sedimentation coefficients  $S_{ij}$  for different size and density ratios (Batchelor & Wen 1982). In equation (1.1)  $S_{ii} = -6.55$ , so the hindered settling function for monodispersed suspensions is recovered for m = 1 (Batchelor 1972).

Davis & Gecol (1994) proposed the following semi-empirical extension of Batchelor's formula:

$$h_i(\boldsymbol{\phi}) = (1 - \phi)^{-S_{ii}} \left( 1 + \sum_{j=1}^m (S_{ij} - S_{ii})\phi_j \right), \tag{1.2}$$

where  $\phi = \sum \phi_j$  is the total volume fraction, and the coefficients  $S_{ij}$  are defined as in equation (1.1). for For  $\phi \to 0$ , equation (1.2) recovers (1.1). For m = 1, equation (1.2) reduces to a power-law form, with exponent  $-S_{ii}$ , similar to the expression of Richardson & Zaki (1954).

The models of Batchelor and Davis & Gecol have been tested in experiments and simulations of bidisperse suspensions (Davis & Birdsell 1988; Al-Naafa & Selim 1992; Abbas *et al.* 2006; Wang & Brady 2015; Chen *et al.* 2023). However, these models are rarely used in practice because they contain a large number of coefficients. Batchelor's model furthermore does not smoothly converge to a form that can handle large solid concentrations, and therefore cannot be used in one-dimensional simulation where the concentration increases from dilute in the supernatant to concentrated in the region immediately above the sediment-supernatant interface. Simpler expressions have therefore been developed for practical predictions of the hindered settling of polydisperse suspensions.

Some authors (Davis & Hassen 1988; Abeynaike *et al.* 2012; Vowinckel *et al.* 2019; Chen *et al.* 2023) have adapted the model of Richardson & Zaki (1954) to the velocity of each class by writing

$$h_i(\phi) = (1 - \phi)^n.$$
 (1.3)

3

This model predicts different velocities for different particle radii  $a_i$ , because  $h_i$  contains the single-particle Stokes formula at denominator. In the current paper, this hindered settling formula will be referred to as Richardson-Zaki's model for polydispersed suspensions. The exponent n is obtained from an empirical fit. For monodispersed suspensions, Richardson & Zaki (1954) originally proposed  $n \approx 5$ , but the exact value is still a subject of debate. For example, Brzinski III & Durian (2018) demonstrated that the value of n depends on the particle Peclet number, and there are two branches in the sedimentation curve which are best fitted by  $n \approx 5.6$  for monodisperse Brownian spheres, and  $n \approx 4.48$  for monodisperse non-Brownian spheres.

Masliyah (1979) and Lockett & Bassoon (1979) proposed the following hindered settling formula:

$$h_i(\phi) = (1 - \phi)^{n-1} \left( 1 - \sum_{j=1}^m \left( \frac{a_j}{a_i} \right)^2 \phi_j \right), \tag{1.4}$$

where  $a_j/a_i$  is the ratio between the radii of the *j*-th and the *i*-th species. The function  $\left(1 - \sum_{j=1}^{m} \left(\frac{a_j}{a_i}\right)^2 \phi_j\right)$  is the hindered settling function obtained by including the effect of volume fraction on the fluid-solid slip velocity, and neglecting the effect of hydrodynamic interactions on the drag force experienced by each particle. The prefactor  $(1-\phi)^{n-1}$  estimates the effect of hydrodynamic interactions on the drag force (see Appendix A, where equation (1.4) is re-derived).

The Masliyah-Lockett-Bassoon (MLB) model is favoured in engineering applications (Xue & Sun 2003; Berres et al. 2005; Dorrell & Hogg 2010). It is easy to tune, since it has only one fitting parameter. Using the MLB model for the stability analysis of settling size-polydispersed and equal-density spheres gives no unphysical lateral segregation and streamers, which are instead obtained using Davis & Gecol's model (Bürger et al. 2002; Tory et al. 2003; Berres et al. 2005). The MLB model has been validated by comparison of predicted and measured concentration profiles (Xue & Sun 2003; Berres et al. 2005). However, this validation is not complete, because the particle concentration is a convolution of the velocities of the different size classes. Therefore a reasonably accurate prediction of concentration does not necessarily imply that the velocity of each class has been predicted correctly. Direct validation of the settling rates predicted by the MLB model for all size classes has not been published.

Despite large recent interest in the modelling of suspensions of wide and continuous size distributions (Pednekar et al. 2018; Gonzalez et al. 2021; Howard et al. 2022; Malbranche et al. 2023; Lavrenteva et al. 2024), there is very limited data on the settling of polydisperse suspensions with many size classes. Most physical experiments have been carried out for bidisperse or tridisperse suspensions (Lockett & Bassoon 1979; Davis & Birdsell 1988; Al-Naafa & Selim 1992; Davis & Gecol 1994; Chen et al. 2023). In these experiments, the largest size ratio between the two species was around 4, and the velocity of the largest size class was only measured in the homogeneous region where a mixture of all size classes was present. Numerical simulations have been carried out for bidisperse suspensions using Stokesian dynamics (Revay & Higdon 1992; Cunha et al. 2002; Wang & Brady 2015) and the force coupling method (Abbas et al. 2006), with size ratio up to 4. Simulations of sedimentation of suspensions with a log-normal distribution have been carried out by Vowinckel et al. (2019) in a domain bounded by top and bottom walls. Their objective was to study the effect of cohesive force on the transient settling process. The velocity of each size class was not quantified.

In this paper, we analyse settling velocity statistics for polydisperse suspensions of non-

Figure 1: A configuration for volume fraction  $\phi = 0.05$  and polydispersity parameter  $\alpha = 0.4$ . The spheres are coloured according to their radii.

Brownian spheres using Stokesian dynamics simulations. The size distribution is log-normal. Of all the particle size distributions, log-normal distributions are the most interesting because of their ubiquitous presence in applications (Vowinckel *et al.* 2019; Di Vaira *et al.* 2022; Rettinger *et al.* 2022). We vary the volume fraction and ratio between the standard deviation and mean value of the particle size distribution. All the particles have the same mass density. The volume fraction ranges from 0.01 to 0.1. The largest size ratio between two classes is 5 and up to 9 classes are considered. To reduce the large statistical error, following other authors (Revay & Higdon 1992; Cunha *et al.* 2002; Abbas *et al.* 2006; Wang & Brady 2015), we produce converged particle velocity statistics by generating a large number of random fixed particle configurations inside a triply periodic box and ensemble-averaging over all the configurations.

# 2. Numerical approach and validation

Consider a polydisperse suspension of *N* spheres having the same density but different radii. The *N* spheres are divided into *m* size classes. The radius of size class *i* is  $a_i$ . Each sphere in class *i* is subjected to a force  $F_i = \frac{4}{3}\pi a_i^3(\rho_p - \rho_f)g$ , which includes the particle weight and buoyancy;  $\rho_p$  and  $\rho_f$  are the densities of the spheres and the fluid, respectively, and *g* is the gravitational acceleration. The single-particle Stokes velocity corresponding to each class is  $u_{St,i} = \frac{2}{9\mu}a_i^2(\rho_p - \rho_f)g$ , where  $\mu$  is the dynamic viscosity of the fluid. In the current work, the particle velocity statistics are calculated from each configuration of the spheres by first averaging over the particles in the computational domain and then ensemble-averaging over statistically identical configurations. Each configuration is generated by randomly placing the spheres one by one inside the computational domain, ensuring that each placement gives no overlap between the spheres (Revay & Higdon 1992; Wang & Brady 2015; Cheng & Wachs 2023). One such configuration is shown in figure 1. In our coordinate system, gravity is aligned in the *z* direction, also referred to as vertical direction in the following. The horizontal direction corresponds to the *x* and *y* coordinates.

To calculate the velocities of individual particles, a basic version of the Stokesian Dynamics

# Focus on Fluids articles must not exceed this page length

Figure 2: Normalized settling velocity vs. volume fraction for a simple cubic array of monodisperse spheres. The line is the point-force solution of Hasimoto (1959). Upward triangles are the numerical results of Brady *et al.* (1988).

method is adopted (Brady *et al.* 1988; Brady & Bossis 1988). The velocities of the spheres are calculated by solving the mobility problem

$$\boldsymbol{U} - \langle \boldsymbol{u} \rangle = \boldsymbol{M} \boldsymbol{F}, \tag{2.1}$$

where U is the 3N vector containing the velocities of the spheres, F is the 3N vector containing the gravitational forces acting on the spheres (these forces include the particle weight and the buoyancy force), and M is the  $3N \times 3N$  mobility matrix (Kim & Karrila 2013). In equation (2.1),  $\langle u \rangle$  is the average translational velocity of the suspension. In our simulations  $\langle u \rangle = 0$ because of the zero volume flux condition of batch sedimentation (Berres *et al.* 2005). Note that in the current work only velocity-force coupling is considered, i.e. the stresslet and other force moments are not considered. Brady & Durlofsky (1988) showed that in a sedimenting suspension the inclusion of the stresslet changes the settling rate negligibly. Because we work in the relatively dilute limit, short-range lubrication are also neglected.

The mobility matrix  $\mathbf{M}$  depends on the positions and radii of the spheres. We used the Rotne-Prager approximation for this term (Rotne & Prager 1969; Zuk *et al.* 2014). This approximation has been shown to give accurate predictions of the sedimentation velocities of suspensions from dilute to relatively dense (Brady & Durlofsky 1988). Triply periodic boundary conditions are applied to the simulation box. The mobility matrix is constructed using the Ewald summation technique by splitting the mobility matrix into a real-space part and a wave-space part (Beenakker 1986). Explicit formulae for the mobility matrix for a polydisperse suspension can be found in Beenakker (1986) and Hase & Powell (2001). As characteristic length and velocity scales, we choose the mean particle radius  $\langle a \rangle$  and the single particle Stokes velocity corresponding to  $\langle a \rangle$ . To make forces non-dimensional we use the effective weight of the mean particle,  $\frac{4}{3}\pi \langle a \rangle^3 (\rho_p - \rho_f)g$ .

In figure 2 numerical predictions for a single sphere in a triply periodic cubic box are plotted against Hasimoto's analytical solution (Hasimoto 1959) and the simulation results of Brady *et al.* (1988). The volume fraction of the simple cubic array is varied by varying the size of the box. Based on the point-force assumption, Hasimoto (1959) derived  $u/u_{St} = 1 - 1.7601\phi^{1/3}$  for  $\phi \ll 1$ , where  $u_{St}$  is the Stokes velocity of the sphere. Brady *et al.* (1988) used Stokesian Dynamics with different approximations for the mobility matrix. The results of Brady *et al.* (1988) shown in figure 2 correspond to simulations in the Rotne-Prager

Figure 3: Normalized relative settling velocity for a pair of spheres as a function of the centre-to-centre distance for (*a*) size ratio 2 and (*b*) size ratio 5. Results of current simulations are shown as symbols, and analytical results of Wacholder & Sather (1974) are shown as lines.

approximation. As seen from figure 2, our results match exactly those of Brady *et al.* (1988) and converge to Hasimoto's solution for  $\phi \rightarrow 0$ . This test validates our implementation of the Ewald summation for the periodic boundary conditions.

In figure 3, the normalized relative settling velocity is shown as a function of the normalized centre-to-centre distance between two unequal spheres with size ratio 2 and 5, respectively. In our simulations, the radius of the large sphere is fixed to  $a_l = 2$ . The radius of the small sphere is  $a_s = 1$  and 0.4 for size ratio 2 and 5, respectively (these values are chosen because the largest radius is 2 and the largest size ratio is 5 in the polydisperse simulations analysed in this paper). The relative settling velocity between the two spheres is normalized by the Stokes velocity of the large sphere. The centre-to-centre distance is normalized by the radius of the large sphere. In figure 3, symbols are results from our simulations, and lines correpond to the asymptotic solution of Wacholder & Sather (1974), in which only far-field hydrodynamic interactions were considered. It can be seen that our results match the analytical solution for both vertically and horizontally aligned pairs.

The current paper discusses results for bidisperse suspensions and polydisperse suspensions with more than two classes, also comparing with the monodisperse case. For the monodisperse case, the radius of the spheres is a = 1. For the bidisperse case, two size ratios are considered:  $a_2/a_1 = 2$  and 5. The radii of the small size classes are  $a_1 = 0.8$  and 0.4 for these two size ratios, respectively. The volume fraction of the small size class is  $\phi_1 = \frac{3}{11}\phi$  for size ratio 2, and  $\phi_1 = \frac{1}{76}\phi$  for size ratio 5. These volume fraction ratios are chosen so that the average radius of the spheres is equal to 1.0 for each system.

For the simulations with several size classes, the particle size distribution follows  $p(a) = \frac{1}{a\sigma\sqrt{2\pi}}e^{-(\ln a-\mu)^2/2\sigma^2}$ , where the mean value of the size distribution is  $\langle a \rangle = e^{\mu+\sigma^2/2}$  and the standard deviation is  $\Delta a = \sqrt{(e^{\sigma^2} - 1)e^{2\mu+\sigma^2}}$ . We define the *polydispersity parameter* as  $\alpha = \Delta a/\langle a \rangle$ . Four size distributions are considered, with  $\langle a \rangle = 1$  and  $\alpha = 0.1, 0.2, 0.3$  or 0.4. Each distribution is cut at the two ends, resulting in a range  $a_{min} \leq a \leq a_{max}$ , where  $a_{min}$  and  $a_{max}$  are chosen so that at least 95% of the original distribution falls within this range. The largest size ratio between two spheres is 5. Each radius range is discretized into between 4 and 9 size classes, with a difference of 0.2 between the radii of two adjacent size classes.

The discrete number frequency distributions are overlaid on the corresponding continuous

Figure 4: Discrete frequency distributions of particle size for different values of the polydispersity parameter (symbols). Lines indicate the continuous log-normal distributions that fit the discrete frequency histograms.

distributions in figure 4. The frequency of size class *i* is calculated as  $\frac{p(a_i)}{\sum_{j=1}^{m} p(a_j)}$ . For each value of  $\alpha$ , the volume fraction  $\phi$  ranges from 0.01 to 0.10. For each simulated case, corresponding to a combination of  $\alpha$  and  $\phi$ , a fixed box size L = 80 is used and 500 random particle configurations are generated. The total number of spheres in each case varies from 925 to 12223.

The average velocity of class i is calculated by ensemble-averaging over M configurations as

$$\langle \overline{u}_{\xi,i} \rangle = \frac{\sum_{k=1}^{M} \overline{u}_{\xi,i}^{k}}{M}, \qquad (2.2)$$

where  $\xi = 1, 2, 3$  correspond to the three Cartesian coordinates,  $\overline{u}_{\xi,i}$  is the intrinsic volume average of the velocity component  $u_{\xi,i}$  within one configuration, and  $\langle \cdot \rangle$  is the ensembleaveraging operator. The intrinsic volume average within class *i* over configuration *k* is  $\overline{u}_{\xi,i}^k = \frac{\sum_{l=1}^{N_i} u_{\xi,i,l}^k}{N_i}$ , where  $N_i$  is the number of particles in class *i*. The standard deviation of a certain

velocity component within one realisation is calculated as  $\left(u'_{\xi,i}\right)^k = \sqrt{\frac{\sum_{l=1}^{N_i} \left(u^k_{\xi,i,l} - \overline{u}^k_{\xi,l}\right)^2}{N_i - 1}}$ . Averaging over many realisations gives an improve estimate of the class-averaged standard deviation. In the bulk of the paper we indicate averages by the bracket symbol, distinguishing between volume and ensemble average when necessary.

# 2.1. Relation between the mobility formulation and Batchelor's formula

In this section we show the connection between the mobility formulation, equation (2.1), and Batchelor's formula, equation (1.1). For simplicity of notation, let us consider a specific size class. Without loss of generality we consider class 1. According to (2.1) the velocity of the  $\alpha$ -th sphere in the 1-st size class is

$$\boldsymbol{u}_{\alpha,1} = \sum_{i=1}^{m} \sum_{\beta=1}^{N_i} \boldsymbol{M}_{\alpha 1,\beta i} \boldsymbol{F}_i, \qquad (2.3)$$

where  $N_i$  is the number of spheres in the *i*-th class, and  $M_{\alpha 1,\beta i}$  is the 3 × 3 mobility matrix representing the hydrodynamic interaction between the  $\alpha$ -th sphere in the 1-st class and the  $\beta$ -th sphere in the *i*-th class (Kim & Karrila 2013). Because  $M_{\alpha 1,\alpha 1} = (6\pi\mu a_1)^{-1}$ , (2.3) can be written as

$$\boldsymbol{u}_{\alpha,1} = \boldsymbol{u}_{St,1} + \sum_{\beta \neq \alpha} \boldsymbol{M}_{\alpha 1,\beta 1} \boldsymbol{F}_1 + \sum_{i \neq 1} \sum_{\beta=1}^{N_i} \boldsymbol{M}_{\alpha 1,\beta i} \boldsymbol{F}_i.$$
(2.4)

The average velocity of the 1-st class in this configuration is

$$\overline{\boldsymbol{u}}_{1} = \boldsymbol{u}_{St,1} + \frac{1}{N_{1}} \left( \sum_{\alpha} \sum_{\beta \neq \alpha} \boldsymbol{M}_{\alpha 1,\beta 1} \boldsymbol{F}_{1} + \sum_{\alpha} \sum_{i \neq 1} \sum_{\beta = 1}^{N_{i}} \boldsymbol{M}_{\alpha 1,\beta i} \boldsymbol{F}_{i} \right),$$
(2.5)

but because  $F_i$  is constant within the same size class we can also write

$$\overline{\boldsymbol{u}}_1 = \boldsymbol{u}_{St,1} + \boldsymbol{s}_{11}\boldsymbol{F}_1 + \sum_{i\neq 1} \boldsymbol{s}_{1i}\boldsymbol{F}_i, \qquad (2.6)$$

where  $\mathbf{s}_{11}$  and  $\mathbf{s}_{1i}$  describe the intra-class hydrodynamic interactions (within the 1-st class) and the inter-class hydrodynamic interactions (between the 1-st and the *i*-th classes), respectively. These two matrices can be written as  $\mathbf{s}_{11} = (N_1 - 1)\overline{\mathbf{M}}_{11}$  and  $\mathbf{s}_{1i} = N_i \overline{\mathbf{M}}_{1i}$ , where  $\overline{\mathbf{M}}_{11}$  and  $\overline{\mathbf{M}}_{1i}$  are the average two-sphere mobility matrices. Upon ensemble-averaging, the average velocity of the 1-st size class can be written as

$$\langle \overline{\boldsymbol{u}}_1 \rangle = \boldsymbol{u}_{St,1} + \langle \boldsymbol{s}_{11} \rangle \boldsymbol{F}_1 + \sum_{i \neq 1} \langle \boldsymbol{s}_{1i} \rangle \boldsymbol{F}_i.$$
(2.7)

The average velocity component in the gravity direction can be written as

$$\frac{\langle u_1 \rangle}{u_{St,1}} = 1 + \frac{9\mu \langle s_{11} \rangle}{2a_1^2 n_1} \phi_1 + \sum_{i \neq 1} \frac{9\mu \langle s_{1i} \rangle}{2a_1^2 n_i} \phi_i,$$
(2.8)

where the formula for the single-particle Stokes velocity is used and  $n_i$  is the number density of class *i*. The scalar  $\langle s_{1i} \rangle$  is the component of  $\langle \mathbf{s}_{1i} \rangle$  for the velocity-force coupling in the gravity direction.

Extending equation (2.8) to a generic class *i* yields

$$\frac{\langle u_i \rangle}{u_{St,i}} = 1 + B_{ii}(\phi)\phi_i + \sum_{j \neq i} B_{ij}\left(\phi, \frac{a_j}{a_i}\right)\phi_j.$$
(2.9)

The dependence of  $B_{ii}$  and  $B_{ij}$  on the volume fraction vector  $\phi$  comes from the fact that  $\langle s_{ij} \rangle$  depends on the pair distribution functions, and the pair distribution functions in turn depend on the volume fraction of each class. The dependence of  $B_{ij}$  on  $a_j/a_i$  comes from the dependence of the two-sphere mobility matrix on the size ratio. For  $\phi \rightarrow 0$ ,  $B_{ii}$  is a constant and  $B_{ij} = S_{ij}$  is only a function of  $a_j/a_i$ . In this limit, equation (2.9) recovers Batchelor's expression (1.1).

## 3. Hindered settling of monodisperse and bidisperse suspensions

The normalised average settling velocity  $\langle u_z \rangle / u_{St}$  for the monodisperse suspension is plotted in figure 5 as a function of  $\phi$ . We include in the plot the Richardson-Zaki correlation  $(1 - \phi)^n$ (Richardson & Zaki 1954) for n = 5, the Batchelor model  $1 + S\phi$  (Batchelor 1972) assuming S = -6.55 and the Hayakawa-Ichiki model  $\frac{(1-\phi)^3}{1+2\phi+1.429\phi(1-\phi)^3}$  (Hayakawa & Ichiki 1995). The

Figure 5: Monodispese case: average settling velocity, normalized by the single-particle Stokes velocity, versus volume fraction

values chosen for the exponent n and the coefficient S here are typically for non-Brownian particles interacting only hydrodynamically (Padding & Louis 2004; Moncho-Jordá *et al.* 2010).

Our simulation results agree with Batchelor's model for  $\phi$  approximately smaller than 0.03. For larger volume fractions, the simulation gives larger values than Batchelor's model. A similar range of validity for Batchelor's model was also found by Abbas *et al.* (2006) using a force-coupling method. Our results also agree well with the Hayakawa-Ichiki model for  $\phi \leq 0.05$  and they lie between the predictions of Richardson-Zaki's correlation and Hayakawa-Ichiki's model for  $\phi \geq 0.06$ . The simulation data for  $\phi = 0.01$  is smaller than the values predicted by the three models. This is expected because of the use of triply-periodic boundary conditions in a domain of finite size (Phillips *et al.* 1988).

Normalised average settling velocities for the small and the large particles in the bidisperse case are plotted as symbols in figure 6 for two size ratios. The predictions of Batchelor's model (equation (1.1)), Davis & Gecol's model (equation (1.2)) and the MLB model (equation (1.4)) are indicated by lines. It is seen from figure 6 (*a*) and (*c*) that our results for the small particles agree with the predictions of Batchelor's model for  $\phi \leq 0.05$ , and lie between the predictions from Batchelor's model and Davis & Gecol's models for  $\phi \geq 0.06$ . For the large particles, our results agree with predictions from Batchelor's model for  $\phi \leq 0.03$  and lie between the predictions from Davis & Gecol's and MLB models for  $\phi \geq 0.04$ . Stokesian dynamics calculations by Wang & Brady (2015) that include stresslet and lubrication contributions also predicted for  $\phi$  larger than around 0.05 hindered settling velocities smaller and larger than those of Davis & Gecol's for the small and the large particles, respectively.

In summary our simulation results for the mono- and bi-disperse cases are comparable to those in the literature.

Figure 6: Bidisperse case: average settling velocity normalized by the single-particle Stokes velocities for the small (left panels) and large (right panels) particles. Panels (*a*) and (*b*) are for size ratio 2. Panels (*c*) and (*d*) are for size ratio 5.

Figure 7: Configuration for different polydispersity parameters and  $\phi$ =0.05, with the spheres coloured according to their settling velocity; (*a*)  $\alpha$ =0, (*b*)  $\alpha$ =0.2, and (*c*)  $\alpha$ =0.4.

# 4. Polydisperse suspensions

To illustrate the spatial distribution of particle velocities in the polydisperse particle simulations, in figure 7 we show snapshots of the simulations with each sphere coloured according to its settling velocity. Spheres coloured in red have settling velocities in the direction of gravity whereas spheres coloured in blue have settling velocities opposite to gravity. Figure 7 (c) shows that the smaller particles can move against gravity, and have negative velocities comparable in magnitude to the positive settling velocity of the largest particles.

Probability distribution functions (PDFs) of horizontal and vertical velocities, shown in figure 8 for different values of  $\alpha$ , are approximately Gaussian, with a variance that increases as  $\alpha$  increases. These PDFs are constructed by considering all the particles in the simulation domain. However, spheres belonging to the same size class also have a distribution of

Figure 8: Probability distribution functions of (*a*) horizontal and (*b*) vertical velocities for different polydispersity parameters and  $\phi$ =0.05.

Figure 9: Probability distribution functions of (*a*) horizontal and (*b*) for  $\alpha$ =0.4 at  $\phi$ =0.05. In contrast to Fig. 8, here the PDFs are calculated based on the distribution of velocities within each size class.

settling velocities. Therefore, in figure 9, we show the PDFs of the horizontal and the vertical velocities of spheres in each size class for  $\alpha$ =0.4. For comparison, the PDFs of the velocities of all the spheres are included in this plot as grey lines. Again, the PDFs are approximately Gaussian (simulations by Cheng & Wachs (2023) of uniform flow past fixed polydisperse random arrays indicate also a Gaussian distribution for the hydrodynamic forces of a given size class). Surprisingly, the PDFs of the horizontal velocities for different size classes collapse onto a single curve (figure 9 (*a*)). From the PDFs of the vertical velocities in 9 (*b*), it is seen that the mean velocity increases as the size of the particle increases. And, different size classes have comparable variances.

The average vertical settling velocity of each size class normalized by the corresponding single-particle Stokes velocity is shown in figure 10 for different values of  $\alpha$ . The inset shows a zoom in the range  $0.8 \le a_i \le 2$ . Because now the settling velocity is normalised by the single-particle settling velocity, the information in this plot complements the data of figure 9 (*b*). We see that for fixed  $\alpha$  the normalized average settling velocity increases as the particle size increases. This means that the velocities of small particles are more hindered than the velocities of large particles. For a given size class, the normalized average settling velocity decreases as  $\alpha$  increases, and decreases faster for small particles than for large particles.

In the previous figures, the total volume fraction was fixed, and  $\alpha$  was changed. In figure

Figure 10: Normalized average settling velocity of each size class for different polydispersity parameters and  $\phi$ =0.05. The inset is a zoom in the range 0.8  $\leq a_i \leq 2$ . The lines are guides for the eyes.

Figure 11: Normalized average settling velocities of each size class, for  $\alpha$ =0.4 and different volume fractions. The inset shows a zoom in the range  $1 \le a_i \le 2$ .

11, we instead change  $\phi$  for fixed  $\alpha$ =0.4. This plot confirms the trend seen in figure 10: for a given volume fraction, the normalized average settling velocity decreases as the particle size decreases. The normalized average settling velocity decreases faster with increasing  $\phi$  for small size particles.

To summarise, the smaller particles are more hindered and more affected by polydispersity than the large ones.

Figure 12: Comparison between the current simulation results and the predictions of hindered settling function models for the average velocity of different size classes, for  $\phi$ =0.05 and different polydispersity parameters: (*a*)  $\alpha$ =0.1, (*b*)  $\alpha$ =0.2, (*c*)  $\alpha$ =0.3 and (*d*)  $\alpha$ =0.4.

### 4.1. Comparison with hindered settling models

In this subsection, current simulations are compared with predictions from Batchelor's (see equation (1.1)), Davis & Gecol's (see equation (1.2)) and MLB (see equation (1.4)) models. The accuracy of Richardson-Zaki correlation (see equation (1.3)) for polydisperse suspensions is also checked. The values of the coefficients  $S_{ij}$  in Batchelor's and Davis & Gecol's models are calculated from  $S_{ij} = -3.50 - 1.10\lambda - 1.02\lambda^2 - 0.002\lambda^3$  where  $\lambda = a_j/a_i$  (Davis & Gecol 1994). The value of the exponent *n* in the MLB model and the Richardson-Zaki correlation is 5.

Hindered settling functions corresponding to different size classes for fixed  $\phi$ =0.05 and different  $\alpha$  are compared against different theoretical models in figure 12. The Richardson-Zaki correlation largely overestimates the hindered settling functions of smaller particles, whereas it gives reasonable values for larger particles. The discrepancy between the Richardson-Zaki correlation and the computed hindered settling functions of smaller particles increases as  $\alpha$  increases. For each  $\alpha$ , the predictions from the other three models show a consistent trend for each size class. The MLB model gives the largest settling velocities, Batchelor's model gives the smallest settling velocities, and Davis & Gecol's model gives intermediate values. The differences between the predictions from these three models get smaller as the particle size increases.

Figure 13 shows the normalized relative differences between the computed and predicted average settling velocities. The Batchelor model and the Davis & Gecol model predict the average settling velocity of each size class quite well for all  $\alpha$  considered here, with relative errors smaller than 10%, except for the smallest size class  $a_i=0.4$  for  $\alpha=0.4$  for which

Figure 13: Relative differences between the average settling velocities from different models and from the current simulations for fixed  $\phi = 0.05$ : (a) Batchelor's model; (b) Davis & Gecol model; (c) MLB model.

the simulation gives a very small settling velocity. From figure 13 (*c*), it is seen that the relative difference between the predictions from the MLB model and the current simulations decreases as  $a_i$  increases, or  $\alpha$  decreases. For  $a_i \ge 1$ , the MLB model predicts the average settling velocities quite well, with the relative difference within 10%. For  $a_i \le 0.8$ , the MLB model starts failing.

Hindered settling function data for fixed  $\alpha$ =0.4 and different  $\phi$  are compared with the predictions from different models in figure 14. Also, Richardson-Zaki's correlation predicts the hindered settling functions of smaller particles poorly. For the other three models, a similar trend in the predicted values is observed as the one in the case of varying  $\alpha$ . The predictions from the MLB model and the Davis & Gecol model are quite close to each other for all size classes at each volume fraction, and they are also quite close to the values from current simulations for larger particles. However, the Davis & Gecol model slightly underestimates the hindered settling functions of the larger particles when  $\phi > 0.06$ . For smaller particles, the predictions from the MLB model and the discrepancies between the predictions from these two models and the values from current simulations get larger as  $\phi$  increases. The predictions of Batchelor's model are close to the simulated values for  $\phi$  approximately less

Figure 14: Comparison between the current numerical results and the predictions of different models. The comparison is here evaluated as a function of  $\phi$  for fixed  $\alpha$ =0.4. (*a*) to (*f*) correspond to size classes  $a_{1,a_2,a_4,a_6,a_7}$  and  $a_9$ , respectively.

than 0.05. As  $\phi$  increases, Batchelor's model underestimates the hindered settling functions of all size classes systematically compared to the results of current simulations.

For fixed  $\alpha$ =0.4, the relative differences between the average settling velocities predicted by different models and calculated by current simulations of each size class for different volume fractions are shown in figure 15. For each size class, the relative difference between the prediction from the Batchelor model and the current simulations increases as the volume fraction increases, and it is within 10% when  $\phi \leq 0.05$ , except for the smallest size class  $a_i = 0.4$ . From figure 15 (b) and (c), it is seen that the relative differences are quite close for the Davis & Gecol and the MLB models, with those of the MLB model slightly larger. For larger size classes ( $a_i \geq 1$ ), both these two models give quite accurate predictions for all volume fractions considered, with the relative differences within 10% compared to the results of current simulations. For smaller size classes ( $a_i \leq 0.8$ ), both these two models give

Figure 15: Same as in Fig. 13, but for different volume fractions and fixed  $\alpha = 0.4$ .

predictions with large relative differences compared to the results of current simulations, and in general the relative difference gets larger as volume fraction increases or as size of the class decreases.

We saw that the MLB model, despite its simplicity, gives relatively good agreement for the large particles. However, it fails for the small particles. The MLB model is based on a closure relation for the particle-fluid velocity difference (see Appendix A). Therefore, to understand the limits of validity of the model, we compute the slip velocity from the simulation data and compare against the MLB model prediction.

Slip velocities for each size class normalized by the corresponding Stokes velocities are plotted in figure 16 for  $\phi$ =0.05 and different  $\alpha$ . The slip velocity for size class *i* is defined as the difference between the average settling velocity of class *i* and the average velocity of the fluid phase,

$$u_{slip,i} = \langle u_{z,i} \rangle - \langle u_f \rangle. \tag{4.1}$$

The value of  $\langle u_f \rangle$  is obtained from the the zero volume-flux condition  $\sum \phi_j \langle u_{z,j} \rangle + (1 - \phi) \langle u_f \rangle = 0$ . The slip velocity predicted by the MLB model is calculated from (see Appendix A)

$$u_{slip,i} = u_{St,i} (1 - \phi)^{n-1}. \tag{4.2}$$

It is seen that the MLB model does not predict accurately the slip velocities of the smaller particles. The discrepancy between the MLB model prediction and the simulation data

Figure 16: Normalized slip velocity for each size class for  $\phi$ =0.05 and different  $\alpha$ . The line shows the prediction of the MLB model.

Figure 17: Normalized slip velocity for each size class for  $\alpha$ =0.4 and different values of  $\phi$ . The dashed line is the prediction of the MLB model.

increases as  $\alpha$  increases. The slip velocities of relatively large particles are reasonably well captured. As the particle size increases, the simulation data tends to converge to the MLB model prediction.

The normalized slip velocities for each size class for fixed  $\alpha$ =0.4 and varying  $\phi$  are plotted in figure 17. It is seen that the prediction of the MLB model gets increasingly worse as the volume fraction increases for the small size classes. Predictions for the largest particles are instead acceptable regardless of the volume fraction.

#### 5. Particle velocity fluctuations

Statistical deviations with respect to the mean particle velocity, as measured by the rootmean square of the velocity fluctuation, increase as  $\alpha$  or  $\phi$  increase (see figures 18 and

Figure 18: Normalized (*a*) horizontal and (*b*) vertical velocity fluctuations for different  $\alpha$  and  $\phi$ =0.05.

Figure 19: Normalized (*a*) horizontal and (*b*) vertical velocity fluctuations for different  $\phi$  and  $\alpha$ =0.4.

Figure 20: Normalized velocity fluctuations of each size class at  $\phi = 0.05$  for (a)  $\alpha = 0.2$ and (b)  $\alpha = 0.4$ .

$\alpha$	horizontal direction	vertical direction
0.1	0.32	1.13
0.2	0.38	1.33
0.3	0.46	1.56
0.4	0.53	1.85

$\phi$	horizontal direction	vertical direction
0.01	0.28	0.95
0.03	0.45	1.54
0.05	0.53	1.85
0.08	0.61	2.08
0.10	0.62	2.15

Table 2: S	Same as t	able 1	but for	different of	⊅ at	$\alpha =$	0.4.
------------	-----------	--------	---------	--------------	------	------------	------

Figure 21: Ratio between vertical and horizontal velocity fluctuation magnitudes for  $a_i = 1$  and (a) different  $\alpha$  at  $\phi = 0.05$ , or (b) different  $\phi$  at  $\alpha = 0.4$ .

19). The normalized horizontal and vertical velocity fluctuations of each size class are shown for  $\alpha = 0.2$  and 0.4 with fixed  $\phi = 0.05$  in figure 20. For a fixed  $\alpha$ , the normalized velocity fluctuations decrease as the particle size increases. Figure 9 seems to suggest that the velocity fluctuations are approximately independent of the particle radius  $a_i$ . Because the Stokes velocity scales as  $a_i^2$ , it is expected that the velocity fluctuations normalized by the Stokes velocity scale as  $\sim a_i^{-2}$ . Our data confirm this scaling (see lines in figure 20):  $u'_i/u_{St,i} = ca_i^{-2}$  fits the data for all the values of  $\alpha$  and  $\phi$  simulated, as shown in tables 1 and 2 (this scaling is also observed in our simulations of bidisperse suspensions, as velocity fluctuations for the two classes are similar in magnitude).

The anisotropy ratio between the vertical and the horizontal velocity fluctuations, plotted

Figure 22: Inter-class interaction term appearing on the right hand side of equation (6.1) for  $a_i = 0.4$  ("small" particles) and  $a_i = 2$  ("large" particles). The particle size distribution corresponds to  $\alpha = 0.4$  and  $\phi = 0.05$ .

Figure 23: (*a*) Interaction coefficients  $S_{ij} - S_{ii}$ and (*b*) volume fraction distribution corresponding to the interaction term of figure 22.

in figure 21, is around 3.5 regardless of the values of  $\alpha$  or  $\phi$ . This value was also observed in the monodisperse and bidisperse simulations.

Peysson & Guazzelli (1999) measured experimentally the velocity fluctuations of small and large particles in a dilute bidisperse suspensions with size ratio 2. They found that the ratio of velocity fluctuations between the small and the large size classes were around 0.85 and 0.75 in the vertical and horizontal directions, respectively, close to  $(a_1/a_2)^{1/2} \approx 0.71$ . To explain their findings, they extended Hinch's scaling for the velocity fluctuations in monodisperse suspensions (Hinch 1988), using two different correlation lengths for the two size classes. In our simulations, the correlation length should be the size of the computational box, as found in other numerical simulations using periodic boxes (Ladd 1996; Nguyen & Ladd 2005) and in other experiments during the initial settling stage of well-mixed suspensions (Segre *et al.* 1997; Tee *et al.* 2002). Using the same correlation length for the two size classes would predict comparable velocity fluctuation magnitudes.

# 6. Discussion

The good comparison between Batchelor's model and the simulation data for sufficiently small  $\phi$  enables us to use this analytical model to illustrate why the prediction of the velocity of the small particles is highly dependent on the full particle size distribution, while that of the large particles is not. Equation (1.1) can be rewritten as

$$h_i = 1 + S_{ii}\phi + \sum_{j=1}^{m} (S_{ij} - S_{ii})\phi_j,$$
(6.1)

where  $S_{ii} = -6.55$  and  $\phi$  is the total volume fraction. The influence of particle class *j* on particle class *i* is negligible if  $|(S_{ij} - S_{ii})\phi_j| \ll |S_{ii}\phi|$ . For  $\phi = 0.05$ , the magnitude of the intra-class interaction term is  $|S_{ii}\phi| = 0.33$ . Let us compare this value to the inter-class interaction term for  $\phi = 0.05$ . In figure 22  $(S_{ij} - S_{ii})\phi_j$  is shown for  $a_i = 0.4$  (small particles) and  $a_i = 2$  (large particles), for  $\alpha = 0.4$ . The maximum absolute value of the inter-class interaction term for the small particle is 0.13, not negligible in comparison to 0.33. The maximum value of the inter-class interaction term for the largest particles is instead 18 times smaller than the intra-class interaction term. The question is: why is the inter-class interaction term small for the large particles? Is this because the interaction coefficients are small in magnitude? Or because of the distribution of volume fractions?

To reply to these questions, in figures 23 (a) and (b) we show  $(S_{ij} - S_{ii})$  and  $\phi$  separately. It is seen that in our log-normal distribution the volume fraction corresponding to the small particles is small in comparison to that of the large particles, and tends to zero as the lower tail of the particle size distribution is approached. The quantity  $(S_{ij} - S_{ii})$  is on the other hand not diverging for  $a_j/a_i \ll 1$ , and is O(1) in this limit. Therefore, the reason why the lower tail of the distribution has a small influence on the upper tail is that the volume fraction corresponding to the lower tail is comparatively small and is weighted by an interaction term that is not large. This is an insight that could be applied to other particle size distributions. For example, if the particle size distribution was such that  $\phi$  was comparatively large in the small particle range, we would expect the settling velocity of the largest particles to be more affected by the smallest particles than seen in our simulations.

The analysis above also gives an insights into the condition for which models parameterised on the total volume fraction can be used as a first, practical approximation for the prediction of the settling of a dilute polydisperse suspension. This approximation is reasonable when the inter-class interaction term is comparatively small. This term is small when either  $\phi_j \ll 1$  for finite  $S_{ij} - S_{ii}$ , the case discussed above. Or when the particle size distribution is narrow so that  $|S_{ij} - S_{ii}| \rightarrow 0$ , the case discussed by Davis & Hassen (1988) (see the value of  $S_{ij} - S_{ii}$ for  $a_j/a_i$  approaching 1 in figure 22 (*a*)). If deviations of  $S_{ij}$  from  $S_{ii}$  are small, then it can be seen from Eq. (2.9) that the hindered settling function for  $\phi \ll 1$  depends only on the total volume fraction. For a dilute suspension with a narrow size distribution, the use of Richardson-Zaki's correlation is for example justified, and is not by chance that the exponent of the Richardson-Zaki correlation ( $n \approx 5$ ) is numerically close to  $|S_{ii}| = 6.5$ . This "lucky coincidence" was also noted by Davis & Hassen (1988).

The comparison with the simulation data shows that the MLB model tends to overestimate the hindered settling functions of particles with sizes smaller than the mean. The MLB model gives more accurate predictions than Richardson-Zaki's correlation for comparatively large particles. MLB is also based on Richardson-Zaki's formula, but in the MLB model the formula is used to estimate the particle-fluid slip velocity, not the absolute settling velocity. For applications where the focus is predicting the sedimentation of the larger particles (e.g., separation of large particles from a polydisperse mixture), using the MLB model could be sufficient. For applications where the stratification in different layers needs to be predicted (e.g. in sedimentology (Dorrell & Hogg 2010)), using the MLB model will overestimate the fraction of the smaller particles in the sediment region. In particle size fractionation by centrifugation or sedimentation (Bonaccorso *et al.* 2013; Backes 2016)), using the MLB model could give a wrong prediction of the region where most of the small particles are located, jeopardising the size fractionation protocol.

Looking at the main assumptions of the MLB model, rederived in the Appendix A, we can see that the model rests on two key assumptions. The first one is that the buoyancy force on each sphere in a polydisperse suspension depends on the suspension density. The conceptual difficulty of modelling the buoyancy force on a small sphere in a suspension of spheres of a different size has been addressed in several papers (Gibb 1991; Di Felice 1995; Ruzicka 2006; Piazza *et al.* 2013). Experiments show that using the density of the suspension to evaluate the buoyancy force gives accurate predictions of the settling velocity of the test sphere when the test sphere is comparable in size or larger than the other particles, but can lead to inaccuracies when the test particle is smaller than the other particles (Poletto & Joseph 1995; Rotondi *et al.* 2015). A second assumption in the MLB model is that the Stokes drag correction for each size class only depends on the total volume fraction, and we have seen that this cannot be in general a good approximation.

We have not tried to improve the MLB model. However, we can give indications on possible approaches for improvement. When the MLB model was derived, no accurate drag correlations for polydisperse sphere arrays were available. Recently, numerical simulation of flow past fixed sphere arrays (van der Hoef *et al.* 2005; Yin & Sundaresan 2009; Sarkar *et al.* 2009; Cheng & Wachs 2023) have shown that data for the drag on polydispersed sphere arrays can be fitted with low-order polynomials of the the first two moments of the size distribution. Improved models for poly-disperse suspensions could therefore be built starting from the MLB model but using the drag force correlation for polydispersed fixed arrays to model the slip velocity. Such models could also account for recent studies on the shear viscosity of polydisperse suspensions (Wagner & Woutersen 1994; Dörr *et al.* 2013; Mwasame *et al.* 2016; Pednekar *et al.* 2018), because in certain limits there is a relation between the drag on a sphere translating through a suspension and the shear viscosity of the suspension (Squires & Mason 2010).

For a continuum size distribution, equation (2.9) which is also valid at non-negligible volume fractions, reads

$$h(a) = 1 + B_{self}\phi + \phi \int (B_{inter} - B_{self})v(a') da', \qquad (6.2)$$

where  $v(a) = \frac{a^3 p(a)}{\int a^3 p(a) da}$  is the normalised volume fraction distribution corresponding to p(a), and the coefficients  $B_{self}$  and  $B_{inter}$  are averages of the mobility matrices. For a twoparameter distribution such as the log-normal, v(a') is a function of only two parameters, for example the mean  $\langle a \rangle$  and the standard deviation  $\Delta a$ . One could therefore postulate a hindered settling function where the inter-class interaction term and the intra-class interaction terms are functions of  $\phi$ ,  $\langle a \rangle$ ,  $\Delta a / \langle a \rangle$ . The issue is that the same functional form should "best fit" a wide range of particle sizes. This is a search which could benefit from the artificial intelligence methods (Zhang & Ma 2020; El Hasadi & Padding 2023; Wu & Zhang 2023; Siddani *et al.* 2024). The analysis we have provided indicate some constraints on this search, for example the functional forms expected for  $\phi \to 0$  or  $\alpha \to 0$ .

# 7. Conclusions

We quantified numerically the hindered settling function of non-Brownian, dilute suspensions of polydisperse spheres with a log-normal size distribution, considering the effects of the polydispersity parameter  $\alpha$  and the volume fraction  $\phi$ .

The average settling velocity  $\langle u_{z,i} \rangle$  of each particle size class is found to decrease as either  $\phi$  or  $\alpha$  increases. The class-averaged velocity  $\langle u_{z,i} \rangle$  decays with  $\phi$  or  $\alpha$  faster for the smaller particles than the largest particles. For given  $\alpha$  and  $\phi$ , the hindered settling function  $\langle u_{z,i} \rangle / u_{St,i}$  decreases as the particle size decreases, indicating that the settling of the smaller size classes is more hindered compared to that of the larger particles.

The probability distribution functions of the horizontal and vertical velocities of each size class tend to follow a Gaussian distribution, with the probability distributions of horizontal velocities of different size classes collapsing onto each other for a given  $\alpha$  and  $\phi$ . The magnitude of the horizontal and vertical velocity fluctuations for each size class increases as  $\phi$  or  $\alpha$  increases, and appear to follow the approximate scaling  $u'_i \sim u_{St,i}(a_i/\langle a \rangle)^{-2}$ . Our simulations for the log-normally dispersed system suggest a value of about 3.5 for the anisotropy ratio between the vertical and the horizontal velocity fluctuations. This value is comparable to the one observed in our simulations for monodisperse or bidisperse suspensions.

To verify the accuracy of available polydisperse hindered settling function models, we compare the predictions of these models with the simulation data. We found that the Richardson-Zaki correlation, which is often used to model polydisperse suspensions, largely overestimates the hindered settling functions of the smaller particles. For  $\alpha$ =0.4 and  $\phi$ =0.05, the value predicted by Richardson-Zaki's formula for polydisperse suspensions can be up to seven times larger than the simulated value. Batchelor's model (equation (1.1)) gives quite accurate predictions for all size classes when  $\phi \leq 0.05$ , yielding discrepancies of the settling velocities that are within 10% of the numerical results. The Davis & Gecol model (equation 1.2) and the MLB model (equation (1.4)) give comparable predictions. Both these models tend to overestimate the hindered settling function of the smaller particles. The discrepancy between the models and the simulation data increases as  $\alpha$  or  $\phi$  increases. In Sec. 6, we use Batchelor's model to analyse the conditions under which models parameterised on the total volume fraction can produce predictions of acceptable accuracy.

Our simulations demonstrate that the modelling of polydispersed suspension is still challenging even in the dilute limit. Practically usable models such as Richardson-Zaki or MLB work reasonably well for large particles, but give significant errors for small particles. This is a major obstacle in the size fractionation by centrifugation, for example, where one is interested in the precise estimation of the velocity of each particle class. In these applications, the small particle fraction is often the most valuable (Backes 2016).

Our results hold in the Stokes regime. For future work, particle-resolved simulations based on the solution of the Navier-Stokes equation around each particle (Uhlmann & Doychev 2014; Fornari *et al.* 2016; Willen & Prosperetti 2019; Yao *et al.* 2021; Shajahan & Breugem 2023) could be used to evaluate the first effect of fluid inertia on our low-Reynolds number observations. In the presence of fluid or particle inertia, averaging over instantaneous random configurations cannot be applied, because in the inertial case the particle velocities depend on the history of the hydrodynamic forces. Thanks to advances in computational power, it is however now possible to simulate tens of thousands particles at finite Reynolds numbers (Breugem 2012; Schwarzmeier *et al.* 2023), and with appropriate time averaging it should therefore be possible to obtain smooth statistics for at least some of the parameters combinations we explore. The most interesting seem to be the extreme cases, namely small deviations from uniformity and log-normals with a large variance (such as our  $\alpha = 0.4$  case). In the presence of fluid inertia, strong trapping of small particles in the wake of large particles is expected.

Experimental techniques such as X-ray radiography (Dulanjalee *et al.* 2020), magnetic resonance imaging (Boyce *et al.* 2016), or optical experiments with fluorescent particles (Snabre *et al.* 2009) could be used to measure the velocity of the small particle fraction in polydisperse suspensions. Machine learning techniques such as symbolic regression (Zhang & Ma 2020; El Hasadi & Padding 2023; Wu & Zhang 2023) could be used in combination with particle-resolved simulations (Yao *et al.* 2022) to extend Batchelor's model to higher volume fractions, or to incorporate into MLB's model information about the moments of the particle size distribution.

### Appendix A. Derivation of the slip velocity closure in the MLB model

A derivation of the MLB model is provided here to highlight the key assumptions of the model, which was too concisely described in the original papers (Masliyah 1979; Lockett & Bassoon 1979). Consider a homogeneous polydisperse suspension with *m* particulate classes. The radius and density of the *j*-th class are  $a_j$  and  $\rho_j$ , respectively, with j = 1, 2, ..., m. The density and dynamic viscosity of the fluid are  $\rho_f$  and  $\mu$ , respectively. Gravity is in the negative *z* direction. Due to the differences between the particle and the fluid densities, a macroscopic pressure gradient dp/dz along the height of the mixture is needed to balance the excess weight of the particles. This pressure gradient drives the back flow of the fluid during settling of the particles. Corresponding to this pressure gradient, each particle experiences a buoyancy force  $F_{\nabla p} = (-dp/dz)V_p$ , where  $V_p$  is the volume of that particle. The total force exerted on each particle by the fluid is given by  $F_{\nabla p}$ , by the buoyancy force due to the undisturbed hydrostatic pressure gradient and by the drag force due to the relative fluid-particle velocity difference.

The steady-state momentum equation for the fluid phase is

$$\left(-\frac{dp}{dz}\right)(1-\phi) - \sum_{j=1}^{m} f_{d,j} = 0,$$
 (A1)

where  $\phi$  is the total volume fraction, and  $f_{d,j}$  is the volumetric drag force density (drag per unit volume) exerted by the *j*-th particle class. The steady-state particle momentum equation for the *j*-th particle class is

$$\left(-\frac{dp}{dz}\right)\phi_j + f_{d,j} - (\rho_j - \rho_f)\phi_j g = 0, \tag{A2}$$

where  $\phi_j$  is the volume fraction of the *j*-th class. Using equations (A 1) and (A 2) gives

$$\frac{dp}{dz} = -\sum_{j=1}^{m} (\rho_j - \rho_f) \phi_j g, \tag{A3}$$

and

$$f_{d,j} = (\rho_j - \rho_{susp})\phi_j g, \tag{A4}$$

where  $\rho_{susp} = (1 - \phi)\rho_f + \sum_{i=1}^{m} \rho_i \phi_i$  is the density of the suspension (see e.g. Xia *et al.* (2022) for the case m = 1). The predictive accuracy of equation (A 4) for small particles immersed in a suspension of larger particles has been put into question (Poletto & Joseph 1995; Rotondi *et al.* 2015).

To calculate the particle velocity, a constitutive equation relating relative velocity to force must be postulated. The MLB model uses a linear law between the drag force and the slip velocity  $u_{slip,j}$  between the *j*-th particle class and the average fluid velocity:

$$f_{d,j} = -\beta_j u_{slip,j}.\tag{A5}$$

where  $u_{slip,j}$  is defined as in equation (4.1). The friction coefficient was calculated as  $\beta_j = \frac{9\mu\phi_jC(\phi)}{2a_j^2}$ . The case C = 1 corresponds to no influence of neighbouring particles on the drag force exerted on a test particle (the factor  $\phi_j$  is due to the fact that  $f_{d,j}$  is a force per unit volume). To model hydrodynamic interactions on the drag force, the MLB model assumes  $C(\phi) = (1 - \phi)^{2-n}$ , as for a monodisperse case at the same total volume fraction (from Richardson-Zaki's correlation, the slip velocity in the monodisperse case is  $u_{slip} = \langle u_p \rangle - \langle u_f \rangle = \frac{\langle u_p \rangle}{1-\phi} = u_{St}(1-\phi)^{n-1}$ ; equating (A 4) and (A 5) using this slip velocity gives  $C(\phi) = (1 - \phi)^{2-n}$ ).

From (A 4) and (A 5), the slip velocity for the polydispersed case is

$$u_{slip,j} = \frac{2a_j^2}{9\mu} (1 - \phi)^{n-2} (\rho_j - \rho_{susp}).$$
(A 6)

If all the particles have the same density,  $\rho_{susp} = (1 - \phi)\rho_f + \phi\rho_p$  and  $\rho_j - \rho_{susp} = (1 - \phi)(\rho_p - \rho_f)$ . In this case the slip velocity simplifies to

$$u_{slip,j} = u_{St,j} (1 - \phi)^{n-1}, \tag{A7}$$

where  $u_{St,j}$  is the Stokes velocity of the *j*-th species. Using the definition of the slip velocity and using mass continuity  $\sum_{i} \phi_{j} \langle u_{j} \rangle + (1 - \phi) \langle u_{f} \rangle = 0$  yields equation (1.4).

It can be seen from the derivation that the main assumptions in MLB's model are embedded in equations (A 4) and (A 5).
