ABSTRACT

We present a study illustrating the effects of the passage of a Large Magellanic Cloud (LMC) mass satellite on the distance and velocity distributions of satellites in Λ +Cold Dark Matter simulations of Milky Way (MW) sized halos. In agreement with previous studies, we find that during such a passage the velocity distribution develops a high-velocity tail due to the reflex motion of the inner part of the halo, which can bias velocity-based virial halo mass estimates. When the velocity distribution of MW satellites is corrected for effects of the LMC passage, it is consistent with the distributions in halos of masses as low as $M_{200c} = 8 \times 10^{11} M_{\odot}$ and as high as $1.5 \times 10^{12} M_{\odot}$. We present a new halo mass estimator $M_{200c} = c \sigma_{3D}^2 r_{med}$, where c is a constant calibrated using satellite systems in the simulated MW-sized halos, σ_{3D}^2 is the variance of 3D velocities taken with the sign of the radial velocity of each satellite, and r_{med} is the median halocentric distance of the satellites. We show that the estimator has only $s = 8\%$ scatter around the median relation of the estimated and true halo masses and deviates by $< 2s$ from the median during the pericentric passage of an LMC-like subhalo. This is because σ_{3D}^2 and r_{med} deviate in the opposite directions during such passages. We apply the estimator to the MW satellite system and estimate the virial mass of the Milky Way of $M_{200c} = 9.96 \pm 1.45 \times 10^{11} M_{\odot}$, in good agreement with several recent estimates using other methods.

Subject headings: galaxies: evolution, galaxies: Large Magellanic Cloud, galaxies: dwarf, galaxies: halos

1. INTRODUCTION

Velocities of galaxies have been long used to infer information about the mass of virialized objects, such as galaxy groups and clusters (Zwicky 1933, 1937; Smith 1936), unvirialized outskirts of such objects (e.g., Diaferio et al. 2005) and gravitationally interacting unvirialized pairs of galaxies (Kahn & Woltjer 1959; Li & White 2008; González et al. 2014; Peñarrubia et al. 2016).

Velocities of galaxies moving in and around the Milky Way (MW) galaxy have also been used to probe its mass under the assumption that such galaxies have negligible tangential velocity or are bound (Sandage 1986; Zaritsky et al. 1989; Kochanek 1996). Boylan-Kolchin et al. (2013, cf. also Sohn et al. 2013), for example, used the velocity of motion of the Leo I galaxy in the outskirts of the MW halo to constrain the virial mass of the Milky Way to $> 10^{12} M_{\odot}$ at the 95% confidence level. At the same time, modeling of the Sagittarius dwarf stream indicated a Milky Way halo mass of $< 10^{12} M_{\odot}$ (Gibbons et al. 2014).

Such differences can be expected because the use of instantaneous velocity and position of individual satellite galaxies to estimate host halo mass is prone to biases if the satellite is in an atypical part of its orbit (Patel et al. 2017a,b). Using the velocities of an ensemble of satellite galaxies can mitigate some of the biases. Watkins et al. (2010) present an estimator of halo mass and use radial velocities of the MW satellites to estimate MW halo mass within 300 kpc distance, but find that the mass estimate is very sensitive to the assumption about velocity anisotropy of the satellite system. At the time, only a limited number of tangential velocity estimates existed and thus esti-

mates of the MW halo mass focused on the Bayesian methods incorporating constraints from individual satellites using the phase-space distribution function calibrated with cosmological simulations of MW-sized halos (Patel et al. 2017a,b, 2018; Eadie et al. 2017).

The dramatic increase in the number of tangential velocity measurements for many MW dwarf satellites and globular clusters with the advent of the Gaia satellite data (McConnachie & Venn 2020c,a; Li et al. 2021; Battaglia et al. 2022) allowed statistical analyses of the velocity distributions using much larger ensembles of objects (Callingham et al. 2019; Eadie & Jurić 2019; Vasiliev 2019; Posti & Helmi 2019; Fritz et al. 2020; Li et al. 2020; Rodríguez Wimberly et al. 2022). Similarly, accurate measurements of phase-space information for stars in the Sagittarius dwarf spheroidal stream and measurements of the LMC velocity allowed for the identification of a clear misalignment between the stream track and the direction of the reflex-corrected proper motions in the leading arm of the stream. Vasiliev et al. (2021) showed that this misalignment is due to the interaction between the LMC and MW, and its modeling allowed them to accurately estimate the total halo masses of both objects.

The improved velocity accuracy and sophistication of the analyses led to reduced uncertainties in halo mass estimates and reduced discrepancies between different studies. Nevertheless, recent MW halo virial mass measurements still allow a fairly wide range of values $\approx 6 - 20 \times 10^{11} M_{\odot}$ (e.g., Vasiliev et al. 2021; Correa Magnus & Vasiliev 2022; Koposov et al. 2023; Zhou et al. 2023; Roche et al. 2024).

One systematic uncertainty in the inferences of halo mass from the positions and velocities of dwarf satellite galaxies and globular clusters is the effect of the Large Magellanic

*kravtsov@uchicago.edu

Cloud (LMC) on the orbits and velocities of such tracers (e.g., Vasiliev et al. 2021; Pace et al. 2022, see Vasiliev 2023 for a review). Effects of the LMC on the nearby stellar streams and dwarf galaxy orbits indicate its halo mass of $1.3 \pm 0.3 \times 10^{11} M_{\odot}$ (Erkal et al. 2019; Vasiliev et al. 2021; Shipp et al. 2021; Correa Magnus & Vasiliev 2022; Koposov et al. 2023; Watkins et al. 2024; Sheng et al. 2024) or $\approx 15\%$ of the MW halo mass.

Such a large LMC mass results in perturbations of orbits of individual MW satellites (Erkal et al. 2020; Pace et al. 2022; Makarov et al. 2023), a significant reflex motion of the inner Milky Way, and asymmetries of the potential in which dwarf satellites and orbit (Gómez et al. 2015; Erkal et al. 2020; Garavito-Camargo et al. 2019, 2021; D’Souza & Bell 2022). These effects have been detected using different tracers in the Milky Way halo (Petersen & Peñarrubia 2020, 2021; Erkal et al. 2021; Conroy et al. 2021). In particular, the reflex motion of the Milky Way affects the velocities of the outer satellites, such as Antlia II (Ji et al. 2021) and Leo I (Erkal et al. 2020). The use of the latter in particular tended to produce higher halo mass estimates in prior analyses. Erkal et al. (2020) also showed that the mass estimator of Watkins et al. (2010) applied to the velocities of satellites and stellar tracers overestimates the enclosed mass $M(< r)$ by up to 50% at large r if the LMC-induced reflex motion is neglected. The presence of the bound Magellanic Clouds pair also affects statistical estimates of the Milky Way halo mass (González et al. 2013). Finally, the approach of the LMC has a large effect on the spatial distribution of MW satellites (Nadler et al. 2020; Manwadkar & Kravtsov 2022; Garavito-Camargo et al. 2023).

Large effects of the LMC on the phase-space distribution of the potential Milky Way tracers need to be accounted for in theoretical inferences of halo mass that use these tracers. This is challenging, however, because only $\approx 5 - 10\%$ of the MW-sized halos have a pair of LMC-like satellite with a pericenter close to ≈ 50 kpc (Boylan-Kolchin et al. 2010; Busha et al. 2011). Thus, large samples of halos need to be simulated with a high resolution sufficient to resolve and model satellite evolution reliably. Alternatively, the analyses can focus on the properties of tracers that are not significantly affected by the dynamical perturbations due to the LMC, such as specific angular momentum (Patel et al. 2018).

In this study, we explore the effects of the LMC on the velocity distribution of satellite systems using a Caterpillar suite of high-resolution simulations of MW-sized halos (Griffen et al. 2016, see Section 2). We demonstrate that similarly to the real LMC, LMC-like objects in simulations induce a reflex motion onto their host halo that creates a high-velocity tail in the distribution of halocentric 3D satellite velocities (Section 3.1). We also show how accounting for this tail affects the conclusion about MW halo mass based on the velocity distribution. We then present a new halo mass estimator that has only $\approx 8\%$ scatter around the true mass when applied to simulated halos (Section 3.2) and which is affected by the LMC-like objects by only $\lesssim 10\%$. We use the estimator calibrated with the simulated halos to infer the MW halo mass of $M_{200c} = 9.93 \pm 1.45 \times 10^{11} M_{\odot}$. We summarize our results and conclusions in Section 4.

2. MODELING MILKY WAY SATELLITE SYSTEM

We model the population of Milky Way dwarf satellite galaxies around the Milky Way using tracks of haloes and subhaloes from the Caterpillar (Griffen et al. 2016) suite of N -

body simulations¹ of 32 MW-sized haloes. We use the highest resolution suite LX14 to maximize the dynamic range of halo masses probed by our modelling.

The haloes were identified using the modified version of the Rockstar halo finder and the Consistent Trees Code (Behroozi et al. 2013), with modification improving recovery of the subhaloes with high fraction of unbound particles (Griffen et al. (see discussion in Section 2.5 of 2016)). As was shown in Manwadkar & Kravtsov (2022, see their Fig. 1), the subhalo peak mass function in the LX14 simulations is complete at $\mu = M_{\text{peak}}/M_{\text{host}} \gtrsim 4 \times 10^{-6}$, or $M_{\text{peak}} \approx 4 \times 10^6 M_{\odot}$ for the host halo mass $M_{\text{host}} \approx 10^{12} M_{\odot}$, even in the innermost regions of the host ($r < 50$ kpc). This is sufficient to model the full range of luminosities of observed Milky Way satellites, as faintest ultrafaint dwarfs are hosted in haloes of $M_{\text{peak}} \gtrsim 10^7 M_{\odot}$ in our model (Kravtsov & Manwadkar 2022; Manwadkar & Kravtsov 2022).

The mass evolution tracks of subhaloes of MW-sized host haloes are used as input for the GRUMPY galaxy formation model, which evolves various properties of gas and stars of the galaxies they host. It is a regulator-type galaxy formation framework (e.g., Krumholz & Dekel 2012; Lilly et al. 2013; Feldmann 2013) designed to model galaxies of $\lesssim L_{\star}$ luminosity (Kravtsov & Manwadkar 2022) which follows the evolution of several key galaxy properties by solving a system of coupled different equations. The model accounts for UV heating after reionization and associated gas accretion suppression onto small mass haloes, galactic outflows, a model for gaseous disk and its size, molecular hydrogen mass, star formation, etc. The evolution of the half-mass radius of the stellar distribution is also modeled. The galaxy model parameters used in this study are identical to those used in Manwadkar & Kravtsov (2022). Importantly for this study, the model was shown to reproduce the luminosity function and radial distribution of the Milky Way satellites and the size-luminosity relation of observed dwarf galaxies (Manwadkar & Kravtsov 2022). Here we use the model to predict luminosities and stellar masses of satellite galaxies around the MW-sized haloes from the Caterpillar suite.

3. RESULTS

3.1. Effect of the LMC on the velocity distribution of satellites

For comparison of Caterpillar-simulated subhalos to Milky Way satellites, we use the distance and velocity measurements found in Table 1 of Rodríguez Wimberly et al. (2022, hereafter RW22). Galactocentric tangential velocities and heliocentric radial velocities are taken from McConnachie & Venn (2020b) and McConnachie & Venn (2020d), while the heliocentric distance and error measurements are from Simon (2019), Karachentsev & Kashibadze (2006), Weisz et al. (2016), and Torrealba et al. (2019). The measurements are converted to the Galactocentric reference frame in RW22.

Comparison to the Milky Way requires a satellite population whose cumulative Galactocentric distance distribution matches that of the MW satellites. To obtain this, we draw a set of random distances from the MW satellite distance distribution using the inverse transform sampling method and spline approximation of the inverse cumulative distribution function of MW satellite distances. We then selected subhalos in each simulated MW-sized halo that were closest to each of the

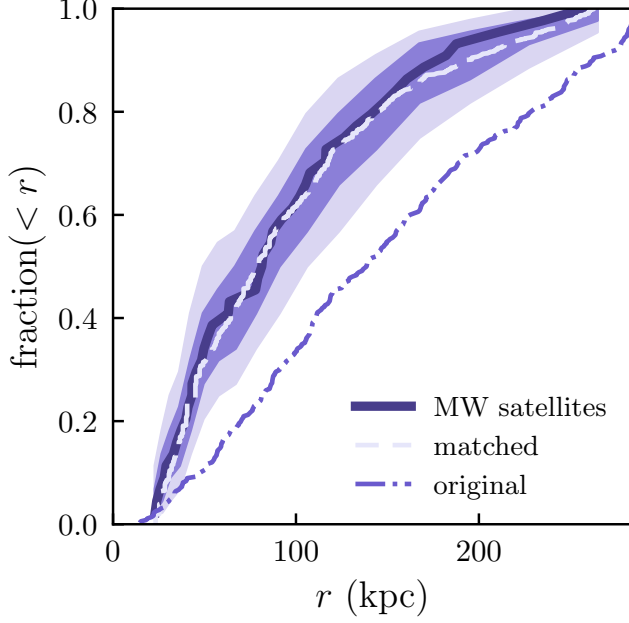

FIG. 1.— The cumulative distribution (CDF) of distances of satellites to the center of their parent halo for the Milky Way satellites (thick solid line). The dark and light-shaded regions show the 68.2 and 95.6 percentiles of the CDFs for the bootstrap resamples of the MW satellite distances at a given distance d . The dot-dashed line shows the cumulative distance distribution of subhalos of a peak mass of $M_{\text{peak}} > 10^8 M_{\odot}$ in the main host halos in the Caterpillar simulations. The light long-dashed line shows the cumulative distribution of the distances for subhalos selected using the distance matching procedure described in the text (Section 3.1). The figure shows that the matching procedure selects subhalos with a distance distribution statistically consistent with that of the Milky Way satellites.

drawn distances. Figure 1 shows that this distance-matching technique produces a satellite population with cumulative distance distribution consistent with the distance distribution of MW the satellites. At the same time, Figure 2 demonstrates that the 3D velocity distribution of the distance-matched subhalos is statistically consistent with the velocity distribution of Milky Way satellites.

Following RW22, we divided the simulated host halos into three mass bins: low mass ($< 10^{12} M_{\odot}$), intermediate mass ($1 - 1.2 \times 10^{12} M_{\odot}$), and high mass ($> 1.2 \times 10^{12} M_{\odot}$). Figure 3 shows the cumulative velocity distribution of satellites in halos in each mass bin and compares them to the velocity distribution of the Milky Way satellites. The intermediate and high mass bins are closest to the distribution of the Milky Way, while the low mass bin is shifted towards lower velocities. Our results are somewhat different from the results shown in Figure 3 of RW22 where the distribution of velocities in halos in the high mass bin is the least consistent with the Milky Way. This is likely due to the difference in the mass distribution of halos in the high-mass bin. The high-mass halos in our sample contain masses in the range $1.2 - 1.6 \times 10^{12} M_{\odot}$, while the sample of RW22 lacks halos in the $1.2 - 1.4 \times 10^{12} M_{\odot}$ range but contains halos of mass up to $1.9 \times 10^{12} M_{\odot}$. The velocity distribution of satellites in their high-mass bin is thus shifted to higher velocities compared to our sample.

Hosts 4 and 53 from the Caterpillar host halo tracks include the passage of subhalos that reach peak masses of $M_{\text{peak}} = 1.16 \times 10^{11} M_{\odot}$ and $M_{\text{peak}} = 1.35 \times 10^{11} M_{\odot}$, respectively. These are comparable to the mass of the LMC with $M_{\text{peak}} =$

FIG. 2.— The cumulative distribution of 3D velocities of satellites in the Milky Way and simulated halos. The velocity distribution of the Milky Way satellites is shown by the thick solid line. The dark and light-shaded regions show the 68.2 and 95.6 percentiles of the CDFs for the bootstrap resamples of the MW satellite velocities at a given velocity v . The dot-dashed line shows the cumulative distance distribution of velocities for subhalos of the peak mass of $M_{\text{peak}} > 10^8 M_{\odot}$ in the main host halos in the Caterpillar simulations. The light long-dashed line shows the cumulative distribution of the velocities for subhalos selected using the distance matching procedure described in the text (Section 3.1). The figure shows that the matching procedure selects subhalos with a velocity distribution statistically consistent with that of the Milky Way satellites.

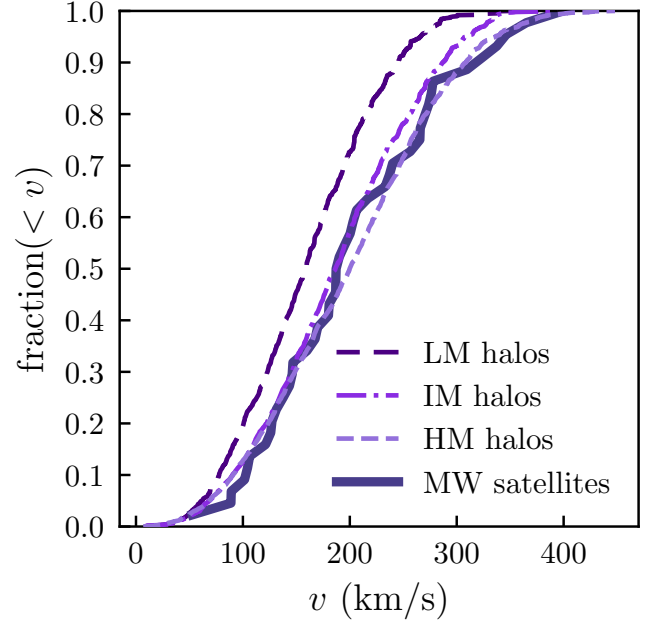

FIG. 3.— The cumulative distribution of 3D velocities of satellites in the Milky Way and simulated halos of different halo mass ranges. The velocity distribution of the Milky Way satellites is shown by the thick solid line. The long-dashed, dot-dashed, and dashed lines show velocity CDFs of satellites in the low, intermediate, and high mass host halo mass ranges. The satellites have been selected using the distance matching procedure described in the text (Section 3.1).

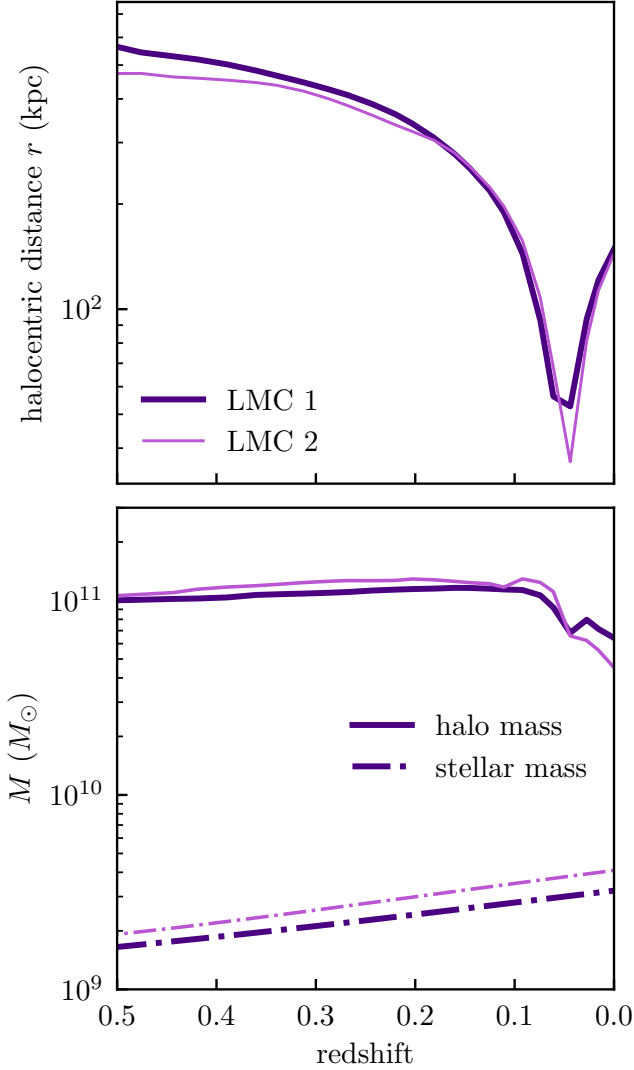

FIG. 4.— *Top panel:* evolution of distance (in physical kpc) of two LMC-like satellites to the center of their host halo from $z = 0.5$ to $z = 0$ in two different Caterpillar host halos. The satellites are on their first infall and reach their pericenter of $\approx 40 - 50$ kpc at $z_{\text{LMC,peri}} \approx 0.04 - 0.05$. *Bottom panel:* Evolution of halo masses (solid lines) and stellar masses (dashed lines) of the two LMC-like satellites shown in the top panel. The satellites reach peak halo masses of $M_{\text{peak}} \approx 1.16 \times 10^{11} M_\odot$ and $M_{\text{peak}} \approx 1.35 \times 10^{11} M_\odot$ at $z \approx 0.1$ before they start to lose mass due to tidal stripping. The stellar mass is computed using our galaxy formation model and continues to grow due to ongoing star formation and reaches $M_\star \approx 3 \times 10^9 M_\odot$, comparable to the stellar mass of the observed LMC.

$1.3 \pm 0.3 \times 10^{11} M_\odot$ (Erkal et al. 2019; Vasiliev et al. 2021; Shipp et al. 2021; Watkins et al. 2024). The time evolution of the halocentric distance and mass of these subhalos are shown in Figure 4. The satellites reach their peak masses $M_{\text{peak}} \approx 1.16 \times 10^{11} M_\odot$ and $M_{\text{peak}} \approx 1.35 \times 10^{11} M_\odot$ at $z \approx 0.1$ and begin to lose mass due to tidal stripping during their pericentric passage at $z \approx 0.05$. As the LMC-like satellites continue to be tidally stripped, stellar mass steadily increases due to continued star formation and reaches a peak of $M_\star \approx 3 \times 10^9 M_\odot$, comparable to the observational estimates of the LMC’s stellar mass.

For one of the host halos, Figure 5 shows the satellite velocity distribution at $z = 0$ and at the time of pericentric passage $z \approx 0.05$, as well as the 15.9 - 84.1 and 2.3 - 97.7 percentile

FIG. 5.— Distribution of satellite subhalos (dots) in the plane of halocentric distance and 3D velocity in one of the host halos in which an LMC-like pericentric passage occurs at $z_{\text{LMC,peri}} \approx 0.05$. The velocities are taken with the sign of the radial velocity of each satellite. The dark and light-shaded bands show the 15.9 - 84.1% and 2.3 - 97.7% ranges of subhalo velocity distribution in distance bins. The large circle in each panel shows the location of the LMC-like satellite. The gray dashed lines show escape velocity profiles for the NFW halo with the same M_{200c} and concentration as the simulated halo at each redshift. The *lower panel* shows the distribution at $z = z_{\text{LMC,peri}}$ and includes the Milky Way dwarf galaxy satellites (stars) for comparison. For reference, the real LMC is at $r \approx 50$ kpc and a total velocity of 320 km/s (e.g., Patel et al. 2018) and has just passed its pericenter. The *upper panel* shows the velocity distribution at $z = 0$, which is approximately symmetric around zero, while at $z_{\text{LMC,peri}}$ it is significantly shifted towards negative velocities.

intervals of the velocity distribution in bins of distance. The effect of the LMC-like satellite is greatest near the pericenter, where the subhalo velocity distribution becomes skewed toward larger negative velocities. At $z = 0$, the velocities return to a symmetric distribution. The effect of the LMC-like subhalo passage on the cumulative velocity distribution is shown in Figure 6, which shows that the satellite distribution has a tail of higher velocities near the pericentric passage. The cumulative velocity distribution at $z = 0$, on the other hand, is similar to the distribution before the LMC-like subhalo entered the host halo at $z = 0.1$. The lower panel of Figure 5 shows that the cumulative distance distribution of satellites becomes

FIG. 6.— Effect of the LMC on the cumulative distribution of 3D velocities $v = |v_{3d}|$ (upper panel) and halocentric distances (lower panel) of satellite subhalos. Dashed lines show the CDFs of satellites of the main host at $z = 0.1$ when the LMC-like satellite was still $\gtrsim 150$ kpc away from the center, while solid lines show the CDFs of satellites at $z = 0$ when the LMC-like satellite is again at $d \approx 150$ kpc (see Figure 4 where this LMC-like object is labeled as LMC1). The dot-dashed lines show the CDFs at $z_{\text{LMC,peri}} = 0.05$ when the LMC-like satellite was close to the pericenter. The velocity distributions are for satellites not selected to match the distance distribution of the MW satellites. Note that the distribution at $z_{\text{LMC,peri}}$ has a significant tail of high-velocity satellites, which is not present in the velocity CDFs at $z = 0.1$ and $z = 0$. The LMC thus significantly skews the velocity distribution towards higher velocities as it passes near the pericenter of its orbit. At the same time, the distribution of distances is skewed towards smaller distances at the LMC pericentric passage.

more centrally concentrated during the pericentric passage of the LMC-like subhalo. Like the velocity distribution, the distance distribution at $z = 0$ becomes closer to the distribution before the passage at $z = 0.1$.

The physical origin of the large change in the velocity and distance distribution of satellites during the pericentric passage of an LMC-like subhalo is the reflex motion of the central region of the MW-sized host halo in response to the gravitational pull of the massive subhalo. During the passage, the mean motion of the host halo relative to the subhalo system is $\approx 40 - 50$ km/s, comparable to the measured magnitude of the Milky Way disk reflex motion (e.g., Petersen & Peñarrubia 2021).

The large effect of the LMC on the velocity and distance distribution needs to be taken into account in the estimates of MW halo mass (Erkal et al. 2020). Although the effect becomes small well after the passage, the LMC in the Milky Way has just passed its pericenter and therefore effects on the MW satellite velocities are expected to be significant. To illustrate the effect of change in velocity distribution on halo mass inference, we approximate the difference in the velocity distributions at the pericentric passage of the LMC-like subhalo and at $z = 0$ as a function of 3D velocity and apply the difference as the correction to the velocity of each observed satellite of the Milky Way.

Figure 7 shows the Kolmogorov-Smirnov (KS) p -values for the consistency between the velocity distributions of distance-matched satellite samples in simulated host halos of different masses and the Milky Way satellites with and without applying this correction. The figure shows the medians of the p -values obtained for the bootstrap resamples of the velocities of the distance-match subhalo and MW satellite samples, while vertical lines show the extent of the 68th percentiles of the p -value distribution of these samples. The figure shows that if the effect of the LMC is neglected, low halo masses are disfavored by the KS test, while intermediate and high-mass halos are consistent with the MW distribution. When the velocity correction is applied, the p -values of the high-mass halos decrease markedly and the distribution of p -values instead peaks in the intermediate halo masses.

The KS test is sensitive to the differences of both the mean shift and the overall shapes of the distribution. RW22 used the Mann-Whitney U test, which is primarily sensitive to differences in the median of distributions. Figure 8 shows the results of the Mann-Whitney test with and without correction for the LMC effect. The points and error bars show medians and 68th percentiles of the p -values estimated for the bootstrap resamples of the velocities of MW satellites and distance-matched satellite subhalos in the simulated host halos. The figure shows results similar to the KS test results in Figure 7. Without the correction, the p -values are high for halos with $M_{200c} \gtrsim 10^{12} M_{\odot}$, while smaller mass halos are disfavored. When the LMC correction is applied to velocities, the p -values for halos with $M_{200c} \gtrsim 1.3 \times 10^{12} M_{\odot}$ decrease substantially, although the overall range of p -values still does not exclude these virial masses.

We note that when the distribution of the p -values for bootstrap resamples is considered, the velocity distribution does not exclude any halos in the mass range of the Caterpillar suite regardless of whether the LMC correction to velocities is applied. The correction only lowers the p -values of halos with $M_{200c} \gtrsim 1.3 \times 10^{12} M_{\odot}$. Thus, the velocity distribution is not a sensitive indicator of halo mass.

FIG. 7.— The distributions of the Kolmogorov-Smirnov test p -values for MW-sized halos in the sample. The vertical lines show the 68 percentile of the distribution of p -values obtained for bootstrap resamples of the satellites in the simulated halos and the Milky Way satellites. The star symbols show the medians of the distributions. *Left panel* shows the p -values computed using velocity distributions not corrected for the effect of the LMC, while *right panel* shows the case when simulated satellite velocities have been corrected to account for the effect of the LMC. The correction significantly diminishes the p -values for halos of $M_{200c} > 1.3 \times 10^{12} M_{\odot}$, but they are still sufficiently high for most halos to be statistically consistent with the Milky Way. In all cases, satellites in simulated halos are selected to match the distance distribution of the MW satellites.

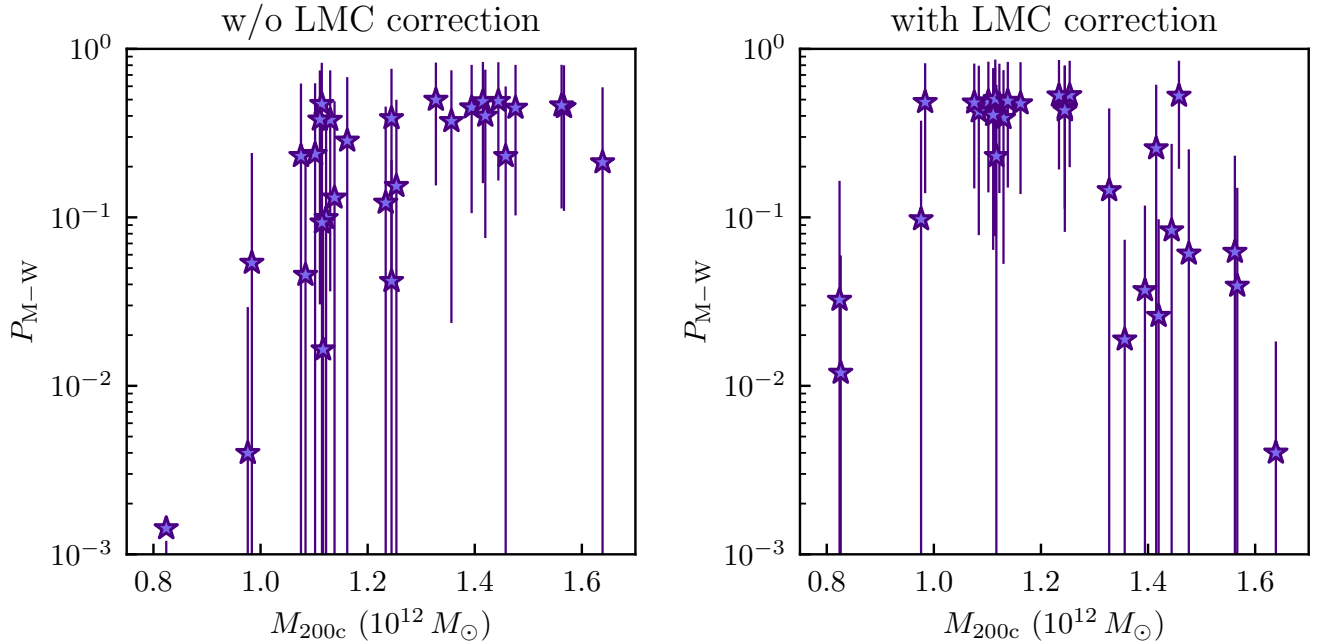

FIG. 8.— The distributions of the Mann-Whitney U test p -values for MW-sized halos in the sample. The vertical lines show the 68 percentile of the distribution of p -values obtained for bootstrap resamples of the satellites in the simulated halos and the Milky Way satellites. The star symbols show the medians of the distributions. *Left panel* shows the case without taking into account the effect of the LMC on the velocity distribution of satellites, while *right panel* shows the case when simulated satellite velocities have been corrected to account for the effect of the LMC. The correction significantly diminishes the p -values for halos of $M_{200c} > 1.3 \times 10^{12} M_{\odot}$. As for the KS test p -values in Figure 7, the correction significantly diminishes the p -values for halos of $M_{200c} > 1.3 \times 10^{12} M_{\odot}$, but they are still sufficiently high for most halos to be statistically consistent with the Milky Way. In all cases, satellites in simulated halos are selected to match the distance distribution of the MW satellites.

FIG. 9.— Upper panel: effect of the LMC on the cumulative distribution function of specific angular momentum of satellites $j = |\mathbf{v} \times \mathbf{r}|$. The distributions are shown at $z = 0.1$ (dashed line), when the LMC-like satellite was still $\gtrsim 150$ kpc away from the center, and at $z = 0$, when the LMC-like satellite is again at $d \approx 150$ kpc (solid line). The dot-dashed line shows the CDF at $z_{\text{LMC,peri}} = 0.05$ when the LMC-like satellite was close to the pericenter. Unlike velocity distribution, the specific angular momentum distribution changes little during pericentric passage of the LMC-sized halo. Lower panel: specific angular momentum distribution of satellites in the MW-sized host halos in the low- ($M_{200c} \leq 10^{12} M_{\odot}$), intermediate ($M_{200c} \in (1 - 1.2] \times 10^{12} M_{\odot}$), and high-mass bins ($M_{200c} > 1.2 \times 10^{12} M_{\odot}$). The dependence of the j distribution on halo mass is weaker than the dependence of the velocity distribution.

Patel et al. (2018) used the specific angular momenta of satellites to estimate MW halo mass and showed that they are not sensitive to deviations from dynamic equilibrium. The upper panel of Figure 9 shows the cumulative distribution of specific angular momentum $j = |\mathbf{r} \times \mathbf{v}_{3D}|$ at three different epochs, $z = 0.1$, $z = z_{\text{LMC,peri}}$ and $z = 0$, for one of the host

FIG. 10.— True halo mass M_{200c} for the 32 host halos in the Caterpillar sample vs the mass $M_{200c,\text{est}}$ estimated using the median satellite distance within 300 kpc, the velocity dispersion of their 3D velocity distribution, and the constant determining using the true M_{200c} of the Caterpillar MW-sized host halos. The white long-dashed line is a one-to-one relation, while dark and light-shaded bands show the 1σ (≈ 0.08) and 2σ scatter of the sample estimated around this relation. The two thin lines show the evolution of the halo mass and its estimate from $z = 0.15$ to $z = 0$ for the two host halos in which the LMC-like satellite passes through its pericenter at $z_{\text{LMC,peri}} \approx 0.04 - 0.05$. Masses estimated for the MW-sized halos using eq. 1 in the sample exhibit a tight linear relation with their true masses with only $\approx 8\%$ scatter.

halos with an LMC-like satellite passing through its pericenter at $z_{\text{LMC,peri}} \approx 0.05$. The effect of the LMC-like satellite on the j distribution is indeed very small, which is consistent with the conclusion of Patel et al. (2018). Thus, the use of the angular momentum to estimate halo mass would not require a correction for the effect of the LMC.

At the same time, the lower panel of Figure 9 shows that the cumulative j distributions for halos in the three mass bins defined above differ considerably less than the distributions of velocity. Specific angular momentum distribution is thus not a very sensitive probe of halo mass. Indeed, the halo mass is proportional to the second moment of the velocity distribution $\langle v^2 \rangle$, while Patel et al. (2018) find that the halo mass depends on the median j of satellites as $M_{200c} \propto j^{1.3}$, and this relation has a large scatter. This motivated us to search for an alternative proxy of M_{200c} which is both sensitive to the value of the mass and robust against effects of the LMC.

3.2. Robust halo mass estimator

The mass of a system in equilibrium should be proportional to a measure of the size of the system and the velocity variance of some tracers of the halo potential. We therefore searched for an estimator of this kind, taking into account that during the LMC passage, the distance distribution of the satellites shifts to smaller distances, while velocity distribution shifts to larger velocities. We find that an accurate estimator of the halo mass enclosing the density contrast of 200 relative to the critical mass, M_{200c} , is given by

$$M_{200c,\text{est}} = c r_{\text{med}} \sigma_{3D}^2, \quad (1)$$

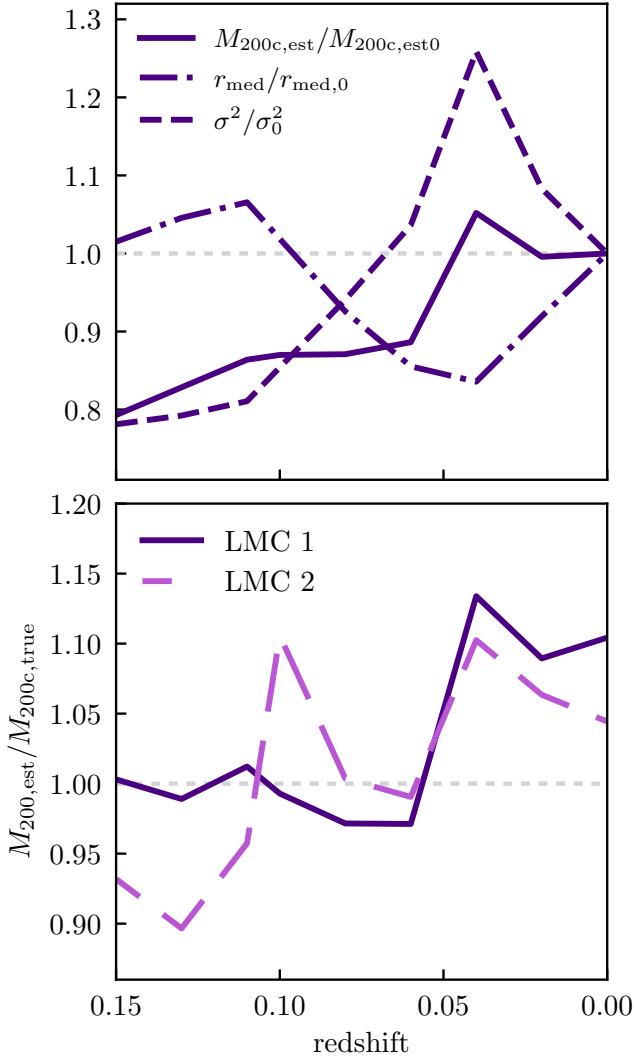

FIG. 11.— *Upper panel:* effect of the LMC on the median halocentric distance of satellites within 300 kpc of the host (dot-dashed line), variance of the 3D velocity σ^2 , and the halo mass estimate from $z = 0.15$ to $z = 0$ in the halo, in which pericentric passage of the LMC-sized object on the first infall occurs at $z \approx 0.04 - 0.05$ when distance to the host is ≈ 50 kpc (see Fig. 4). All quantities are normalized to their values at $z = 0$. Note that the LMC induces an upward fluctuation of σ^2 but a downward fluctuation of d_{med} . These fluctuations thus offset each other in the estimate $M_{200c,est}$ using eq. 1, which exhibits a fluctuation of only $\approx 10\%$. *Lower panel:* the ratio of the halo mass estimated using equation 1 to its true mass during the LMC-sized object’s pericentric passage. Prior to the pericentric passage, eq. 1 provided an unbiased estimate of M_{200c} . During and immediately after the passage, the estimate is biased by $\approx 5 - 10\%$.

where the constant $c = 2.85 \pm 0.028 \times 10^5 M_\odot$ estimated using the true values of M_{200c} of the 32 Caterpillar host halos, r_{med} is the median halocentric distance of the satellites within $r_{max} = 300$ kpc in kiloparsecs, and σ_{3D}^2 is the variance of $v_{3D} \times v_r/|v_r|$ for satellites within r_{max} in units of kilometers per second. Note that the variance of velocities with the sign of radial velocities is used here, not just the variance of the absolute values of v_{3D} . This variance measures the width of the 3D velocity distribution of halo satellites shown in Figure 5.

Figure 10 demonstrates that the accuracy of this halo mass estimator is not significantly impacted by the passage of the

LMC. The ratio of the halo mass obtained using the estimator to the halo mass given by Caterpillar for each host shows only $s \approx 8\%$ scatter around the 1:1 ratio. The light lines show the evolution of the estimated versus true mass for the two host halos with an LMC-like satellite from before its infall at $z = 0.15$ to $z = 0$, well after its pericentric passage. The estimator stays within the $2s$ range through the duration of the satellites’ passages, indicating that the estimator is not overly sensitive to the effects of an LMC-sized satellite.

The upper panel of Figure 11 shows the evolution of the factors of eq. 1 compared to their values at $z = 0$ as a function of redshift. At $z = 0.04 - 0.05$, when the LMC-sized satellite is closest to the host, the median halocentric distance of the satellites decreases while the variance of the 3D velocity distribution increases. This reflects the changes in the velocity distribution and distance cumulative distribution shown in Figures 5 and 6. As a result, the value of the estimated mass deviates from its $z = 0$ estimate by less than 10% during the pericentric passage of the LMC-like satellite at $z \approx 0.04$.

The lower panel of Figure 11 shows the evolution of the ratio of the estimated halo mass to the true mass from $z = 0.15$ to $z = 0$. It shows that during and after the pericentric passage, the estimated mass is $\approx 10\%$ higher than the true mass. Thus, given that the scatter around the relation is $\approx 8\%$, the LMC passage biases the mass by 1.25σ . This means that the mass estimator of eq. 1 is robust against effects of the LMC passage. The small 10% correction due to the effect of the LMC can be applied to the mass estimate of the Milky Way.

With the proportionality constant obtained from the simulated halos, using eq. 1 with all of the Milky Way satellites with measured 3D velocities and applying 10% correction for the effect of the LMC yields a Milky Way halo mass of $M_{200c} = 9.96 \pm 1.45 \times 10^{11} M_\odot$, where uncertainty is estimated using bootstrap resampling. If we use only the classical satellites of the Milky Way ($M_V < -8$) we get a consistent estimate $M_{200c} = 8 \pm 2.4 \times 10^{11} M_\odot$, albeit with a larger uncertainty.

4. SUMMARY AND CONCLUSIONS

We presented a study illustrating the effects of the passage of LMC-mass satellites on the distance and velocity distributions of satellites in the Milky Way-sized halos. We also considered the effect of such passages on their mass estimates. Our results and conclusions are as follows.

1. In agreement with results of Erkal et al. (2020), we find that the effect of the passage of an LMC-like satellite on the velocity distribution is substantial and this effect can bias mass estimates based on velocities. We show that during the pericentric passage, the velocity distribution develops a high- v tail due to the reflex motion of the inner part of the halo, while the satellite spatial distribution becomes more centrally concentrated.
2. We show that correcting for the effect of the LMC on the 3D velocity distribution of satellites when using this distribution to estimate halo mass favors halo masses in the range $1 - 1.3 \times 10^{12} M_\odot$. However, we also show that the velocity distribution is a rather low accuracy estimator of halo mass as velocity distributions in halos of masses as low as $M_{200c} = 8 \times 10^{11} M_\odot$ and as high as $1.5 \times 10^{12} M_\odot$ are still statistically consistent with the velocity distribution of the MW satellites.
3. We considered the distribution of specific angular momenta j as an estimator of mass and confirmed that the

j distribution is not sensitive to the passage of LMC-mass satellites. At the same time, we find that the j distribution is a weak function of host halo mass and is therefore a relatively poor mass indicator.

4. We present a new halo mass estimate that is proportional to the variance of 3D velocities taken with the sign of the radial velocity of each satellite and the median halo-centric distance of the satellites (eq. 1). The velocity variance is a measure of the width of the velocity distribution shown in Figure 5. The estimator has only 8% scatter around the mean $M_{200c,est} - M_{200c}$ relation.
5. We show that the velocity variance and median distance deviate in opposite directions during the pericentric passage of the LMC-like satellites (Fig. 11). For this reason, the estimator deviates by $< 2s$, where s is the scatter around the median $M_{200c,est} - M_{200c}$ relation during the pericentric passage of the LMC-like subhalos.
6. We apply the estimator to the MW satellite system and estimate the virial mass of the Milky Way to be $M_{200c} = 9.96 \pm 1.45 \times 10^{11} M_{\odot}$, in good agreement with several recent estimates using other methods.

ACKNOWLEDGEMENTS

We are grateful to Vasily Belokurov and the UChicago structure formation group for useful discussions during this project. We thank Alexander Ji and the Caterpillar collaboration for providing halo tracks of the Caterpillar simulations used in this study. AK was supported by the National Science Foundation grants AST-1714658 and AST-1911111 and NASA ATP grant 80NSSC20K0512. SW was supported by the University of Chicago CCRF's Quad Research Scholarship program. Analyses presented in this paper were greatly aided by the following free software packages: NumPy (Van Der Walt et al. 2011), SciPy (Jones et al. 01), Matplotlib (Hunter 2007), and GitHub. We have also used the Astrophysics Data Service (ADS) and arXiv preprint repository extensively during this project and the writing of the paper.

DATA AVAILABILITY

Halo catalogs from the Caterpillar simulations are available at <https://www.caterpillarproject.org/>. The GRUMPY model pipeline is available at <https://github.com/kibikov/GRUMPY>. The data used in the plots within this article are available on request to the corresponding author.
